excited to emit blue light (450 nm) by near-UV light (340 nm). NADH and NADPH fluorescence is highly quenched in the cytosol. Consequently, nearly all NADH and NADPH fluorescence arises from mitochondria. The green fluorescence of oxidized flavin can also be used to monitor the oxidation–reduction of flavoproteins in mitochondria and elsewhere.

3.3.4 Molecular Markers

Recently, the GFP of the jelly fish *Aequorea victoria* has emerged as an important fluorescent reporter of gene expression and protein localization in living cells. GFP is a 27 000-Da monomer consisting of 238 amino acids in an 11-stranded \(\beta\)-barrel surrounding a coaxial \(\alpha\)-helix containing the chromophore. Wild-type GFP absorbs near-UV and blue light and emits green light with a maximum at 509 nm. Several red- and blue-shifted GFP mutants have been developed to increase brightness and yield emissions of blue, cyan and yellow in addition to green.

To use GFP, fusion constructs are made of the cDNA for GFP and a cDNA of a target protein. After gene transfer by transfection or other means (e.g. viral vectors), living cells use this DNA to synthesize a fusion protein comprised of the target protein and its GFP tag. Using fluorescence microscopy, the subcellular localization and intracellular trafficking of the GFP fusion protein can then be followed in the living state (Figure 10a and b). Fluorescence resonance energy transfer occurs between the different-colored GFP mutants and is the basis for the development of unique new chimeric indicators. For example, \(\text{Ca}^{2+}\)-indicating fluorophores have been developed by fusing cyan-emitting fluorescent protein (CFP) with calmodulin and yellow-emitting fluorescent protein (YFP). \(\text{Ca}^{2+}\) binding then alters fluorescence energy transfer between CFP and YFP. These proteins are called cameleons and can be imaged by fluorescence microscopy.

4 CONCLUSIONS

Fluorescence microscopy is a powerful tool to identify and localize specific molecular components with lateral resolution of 0.2 \(\mu\)m. New techniques of confocal and multiphoton microscopy also permit an axial resolution approaching 0.8 \(\mu\)m even in thick specimens. Unlike electron microscopy, fluorescence optical microscopy allows nondestructive observation of living cells and tissues. The number of specific parameter-indicating fluorophores useful for live-cell imaging continues to increase. These include markers of cell shape and volume, organelles, membrane potentials, ions and other chemical constituents. With the advent of GFP and its many mutants, virtually any cellular protein can be fluorescently tagged in the living state. These developments make fluorescence microscopy an indispensable tool for the molecular biologist, cell biologist, physiologist and others, both inside and outside the life sciences.

REFERENCES

This article provides an overview of the general properties of organized assembly (ordered media) systems, such as aqueous surfactant and bile salt micelles, lipid (liposomes) and surfactant vesicles, and cyclodextrins (CDs), and summarizes their utilization to enhance the performance of analytical fluorescence measurements. In many instances, organic molecules and metal complex species when included within a CD cavity or solubilized and bound to surfactant aggregates exhibit enhanced fluorescence, improving detectability of such analytes. The altered microenvironment within the organized medium can impede the interfering action of other species (inorganic or organic) present in the sample matrix, which often improves the selectivity of the analytical method. These benefits of improved sensitivity and selectivity arise from the compartmentalization, isolation, and shielding of the excited singlet state of the guest analyte from quenching and nonradiative decay processes, as well as preventing side reactions that otherwise can occur in bulk solution (or sample matrix). Organic solvents or time-consuming extraction steps can also be avoided, owing to the increased solubility of nonpolar organic or inorganic reagents and/or analyte molecules in water in the presence of the organized medium, allowing the use of an aqueous medium to perform the procedure. The possibility of conducting reactions and forming fluorescent organic or metal chelates in micellar (or other organized) media that are not observed in a bulk homogeneous solvent system serves to expand the scope of possible chemistries for design/development of new, unique, and improved fluorescent assays. Examples of fluorescent methods for determination of both organic and inorganic analytes are provided, which serve to illustrate the advantages and benefits accrued from the use of the micelles, vesicles, liposomes, or CDs in such procedures, along with experimental considerations and cautions in utilizing organized media.

1 INTRODUCTION

The past 35 years has witnessed ever-increasing interest in and utilization of the effects of organized assemblies (also termed ordered media) on photophysical and photochemical processes and reactions. Reactants accommodated in such assemblies, i.e. normal and reversed micelles, vesicles and liposomes, CDs, etc., often achieve a greater degree of organization and altered microenvironment compared to that in bulk homogeneous solution, which may promote unique general properties and reaction features, characteristics which may mimic processes in biosystems and have wide applications in chemical analysis and separation science.

This article focuses on several types of aqueous-based organized assembly (also referred to as ordered media or membrane mimetic) systems and their utilization to enhance analytical luminescence measurements. Included for discussion are the aqueous (normal) surfactant and bile salt micelle, aqueous synthetic surfactant vesicle and liposome, and aqueous CD systems. Following a brief description of these different organized assemblies and their basic properties, examples of applications involving such media in the area of analytical luminescence spectroscopic measurements. The goal is to present a general overview of the different possible beneficial roles and uses of such media in analytical luminescence spectroscopic measurements. The overview is intended to be more applied and illustrative in nature rather than being a comprehensive discussion of all the voluminous reported work in this area. For more fundamental information and details on the fluorescence technique in general, the reader is referred to a monograph on this topic.
2 BRIEF DESCRIPTION OF ORGANIZED ASSEMBLIES

Of the many different organized assemblies and supramolecular systems reported in the literature, this article restricts itself to those surfactant aggregate systems and CD hosts that exist in aqueous solution. This choice was dictated by the fact that most of the reported applications in analytical fluorescence measurements have utilized such media. Detailed discussion of all aspects and salient features of the chemistry and properties of such surfactant and CD ordered media is beyond the scope of this article. More fundamental information on these systems can be obtained by consulting the cited monographs, reviews, and research articles on desired topics mentioned herein.

2.1 Survey of Surfactant Aggregate Systems

Surfactant (detergent) molecules, which contain an alkyl hydrophobic chain (tail) and a polar head group, are capable of forming aggregate supramolecular assemblies that exhibit properties distinctly different from those of the individual monomers prior to aggregation. Depending on the lipophilic–hydrophilic balance, a variety of aggregate morphologies, such as normal micelles, rods, disks, planar bilayers, vesicles, liposomes, and hexagonal phases, among others, have all been observed. With increasing surfactant concentration, morphologies ranging from micelles (L₁), through a cubic array of micelles (I₁), hexagonally packed rods (H₁), cubic bicontinuous spheres (V₁), to lamellae (L₃) where phase inversion takes place, and inverted morphologies develop. Among these, this overview focuses on just the normal aqueous surfactant and bile salt micelle, liposome, and synthetic vesicle systems. A monograph addresses the use of reverse micelles in chemical analysis, including their utilization in fluorescence measurements.

2.1.1 Normal Surfactant Micelles

In terms of actual analytical applications, aqueous (or normal) surfactant micelle systems have probably been the most frequently employed form of surfactant-based organized media in chemical analysis applications. Normal micelles are formed in aqueous solution by the aggregation of amphiphilic surfactant molecules. In simplest terms, the micellar entity is considered to be a globular structure in which the alkyl hydrocarbon core region is surrounded by a hydrophilic outer region comprising the surfactant head group (which can be cationic, anionic, zwitterionic, or nonionic), counterions, and water molecules (Figure 1). The minimum surfactant concentration required for micelle aggregate formation is referred to as the critical micelle concentration (CMC). At concentrations below this value in solution, the surfactant molecules exist as solvated monomers. The number of individual surfactant molecules present in a micelle aggregate is referred to as the aggregation number (N). Typically, such aggregates contain 60–150 surfactant molecules. It should be stressed that the micellar species is not a permanent (bonded) entity, but a dynamic structure that exists in equilibrium with its monomers, with the monomeric...
surfactant molecules both entering and exiting the micelle.\(^{(11,12,18,21,22)}\)

The CMC values for surfactant micelles have been determined from breaks in plots of the luminescence intensity of an organic probe molecule as a function of surfactant concentration as a consequence of alteration of the microenvironment experienced by the probe upon formation of and binding to the micelle aggregate.\(^{(12–92)}\)

Table 1 includes the CMC values for some classic micelle-forming surfactants. CMC values can be altered owing to the presence of the analyte and any other components required to adjust the pH and/or ionic strength.\(^{(93–99)}\) For instance, the CMC of sodium dodecyl sulfate (SDS) in water was determined as 0.1 g per 100 mL, whereas a value of 0.2 g per 100 mL was observed in the presence of 120 ppm of the analyte, fenproporex.\(^{(96)}\) The CMC of SDS was likewise altered from 8.1 mM in water to 1.1 mM in the presence of 0.125 M NaCl;\(^{(22)}\) whereas the CMC of cetyltrimethylammonium chloride (CTAC) (hexadecyltrimethylammonium chloride) was 1.3 mM in water, it was only 0.28 mM in an aqueous 0.010 M NaOH solution. For cetyltrimethylammonium bromide (CTAB) (hexadecyltrimethylammonium bromide), the CMC in water is 0.92 mM, whereas it is 0.31 mM in the presence of 1.0 M sulfuric acid.\(^{(100)}\) The CMC of SDS increased from 8.1 to 15.0 mM in the presence of 6.0 M urea whereas that of Triton X-100 changed from 0.20 to 0.60 mM in the presence of 3.0 M urea.\(^{(73)}\)

(continued overleaf)
some cases, the presence of another hydrophobic species, particularly dye molecules, can induce micellization of surfactants. Such aggregated species are sometimes referred to as dye-rich induced micelles. Addition of CDs can also induce aggregation of ionic surfactants at concentrations below their normal CMC. The CMC and aggregation number of aqueous normal micelles were found to be almost independent of pressure. Typically, there is a slight increase in the CMC of ionic surfactants with increased temperature above ca. 30 °C. The microviscosity is temperature dependent; for instance, for SDS varies from 6 cP at 30 °C to 13 cP at 100 °C and 17 cP at 0 °C; similarly, the values for CTAC are 18, 49, and 70 cP, respectively, for the same temperatures.

Typically, the presence of 20–40% (v/v) of organic cosolvents (such as methanol, ethanol, and acetonitrile) in water precludes micelle formation. In fact, this has been observed using fluorescent compounds, i.e. drastic reductions in fluorescence intensity (FI) in this range of added cosolvent.\(^\text{116–113}\) Dilution of micelle-containing solutions with water can also result in destruction of the micelles if the final surfactant concentration is below the CMC for that surfactant.

A number of monographs provide a more complete description of surfactant and micellar systems and their properties and salient features.\(^\text{6,11,12,18,21,94,114–116}\)

### 2.1.2 Bile Salt Surfactant Aggregate Systems

In comparison with the classical linear aliphatic surfactants, the bile salts have a different molecular structure and stereochemistry. The bile salts are rigid, facial amphiphilic molecules and do not contain the usual polar head group and apolar tail of the classic micelle-forming surfactants. Instead, they possess a steroidal ring structure and are crescent shaped, with the hydrophobic convex side containing the hydrocarbon elements of the steroid ring along with the angular methyl groups, while the more polar concave side bears the hydroxy substituents.\(^\text{117,118}\) When bile salts are dissolved in water, they also form aggregate species termed micelles above the CMC, as do classical linear anionic surfactants. However, their aggregation behavior is more complex, showing more gradual (and successive) changes in aggregate size with concentration. Bile salt aggregates in aqueous solution consist of transient species (i.e. monomers, dimers, tetramers, ..., higher oligomers) in dynamic equilibrium with one another. The relative population of these structures is very sensitive to the conditions of the solution, being influenced by the concentration of the bile salt, the absence or presence of additives in the system, and the temperature.\(^\text{118,119}\) Table 1 also provides the CMC values for some bile salt surfactant micelle systems.

Bile salt aggregation is viewed as stepwise formation of globular primary bile salt micelles consisting of 2–10 monomers held together by hydrophobic interactions between the nonpolar backs of the bile salt molecules which constitute the interior region with the more polar hydroxyl and carboxylate groups projecting outward and accessible to water molecules according to the Small model. In the next stage, at high bile salt concentrations (and/or added salt), larger secondary bile salt aggregates are formed by mutual association of the primary micelles as a consequence of intermolecular hydrogen bonding between the primary micelle’s bile salt hydroxyl and side-chain groups.\(^\text{117}\) In addition to this model, a helical model for bile salt aggregates has also been proposed.\(^\text{119}\)

In general, it is thought that bile salt aggregate systems are more hydrophilic than conventional SDS micelles.\(^\text{120}\) The bile salt micelle systems are less surface active than conventional aqueous normal micelles.\(^\text{119}\) As a consequence, bile salt micelle solutions do not form suds/foam as much; this is very useful in the preparation and manipulation of such solutions, especially if gas purging is required as in some fluorescence measurements.\(^\text{121}\) The micellar properties of bile salts, such as sodium taurocholate (NaTC), are relatively insensitive to experimental conditions.\(^\text{122}\) Thus, compared with the normal aqueous micellar systems, the bile salt media are also much more versatile and flexible in terms of their tolerances of pH, ionic strength, temperature, and counterion concentrations and are less likely to precipitate.\(^\text{121,123}\) Bile salt solutions can tolerate the presence of greater concentrations of additives, such as organic solvents, compared with conventional micelles such as SDS, without disruption of their aggregate structure.\(^\text{119,124}\) They are therefore more robust aggregate systems than traditional aqueous normal micelles.\(^\text{122}\) In addition, bile salts and their micellar aggregates are chiral entities, so they can function as a chiral selector and differentially bind the enantiomers of some organic compounds.

A monograph provides additional information on bile salt/acid systems and their utilization in chemical analysis applications.\(^\text{125}\)

### 2.1.3 Liposome/Synthetic Vesicle Systems

Amphiphiles with long alkyl double chains such as the phospholipids or some synthetic amphiphiles form aqueous compartments enclosed by a lipid–surfactant bilayer, known as vesicle or liposome aggregate systems, when dispersed in aqueous solution. The hydrocarbon tails of the lipid or surfactant molecules are sequestered inside the bilayer, and the polar head groups stick out into the aqueous phase – inside and outside the compartment.\(^\text{126}\) A macroscopically isotropic small unilamellar vesicle (SUV) can be formed via ultrasonic solvation of a lipid or surfactant solution above its phase transition temperature.\(^\text{127,126}\) Alternatively, SUVs can be prepared by injecting/infusing a small aliquot of an ethanolic solution of the lipid through a thin needle into a rapidly stirred buffer solution at a temperature 15°C higher then the transition temperature of the phosphatidylcholine (PC) lipid employed.\(^\text{129,130}\) The lamellar phase transition temperature (\(T_\text{M}\)) of dimyristoylphosphatidylcholine (DMPC),
dipalmitoylphosphatidylcholine (DPPC) and dimyristoylphosphatidylserine (DMPS) are 20–24, 34–42, and 31–39 °C, respectively. The latter recipe produces SUVs having an average diameter of 25–50 nm. A large unilamellar vesicle (LUV) can also be prepared from such a lipid by variation of the preparation conditions to yield vesicles (liposomes) with a radius in the range 0.05–5 µm. Such monolamellar vesicles can also be prepared by the so-called detergent method. Several reports provide recipes for the different methods of vesicle/liposome preparation, the type(s) of liposomes formed by each, and their advantages/disadvantages.

In addition to the multilamellar vesicle (MLV) (multicompartment, onionlike structure) type, whose diameters are in the range 1000–8000 Å, the unilamellar systems can also be prepared from lipids such as egg PC, bovine phosphatidylserine (PS), and egg phosphatidylglycerol (PG). Some synthetic surfactants can also produce bilayer aggregates. In particular, double-chain ammonium amphiphiles such as didodecyldimethylammonium bromide (DDAB), dihexadecylphosphate (DHP), and dioctadecyldimethylammonium chloride (DODAC) or dioctadecyldimethylammonium bromide (DODAB) also belong to a representative class of such bilayer-forming compounds. The phase transition temperature for DODAC vesicles is 37 °C. For vesicle systems formed by dispersing lipid or synthetic surfactant molecules in aqueous medium, there are two types of water molecules present in the system – those in the bulk and those enclosed within the water pool of the vesicle (liposome). In general, the water pool of vesicles is much larger in comparison with that in reverse micelles. Vesicles/liposomes are dynamic aggregate systems since they can exhibit phase transition and fusion behavior and are osmotically active. For most analytical applications, the single-compartment bilayer liposomes (or vesicles) formed by the sonication method are probably “best” since they possess a more uniform size distribution and can be more reproducibly prepared. Purification of liposomes from the free monomeric lipid, detergent, and unencapsulated solutes can be accomplished either by gel filtration chromatography or dialysis.

Although there are many similarities in properties between surfactant vesicles/liposomes and micelles, there are some important and notable differences. Structurally, the interior volume of vesicle/liposome aggregates consists of an encapsulated aqueous solution in contrast to that of micelles whose interior comprises the hydrophobic alkyl chains of the surfactant. The surfactant vesicles are much larger, more rigid (less fluid), and more static aggregate entities, particularly at temperatures below their phase-transition temperature.

Although vesicle aggregate structures are in equilibrium with their monomer, in most instances, the monomer concentration is fairly low (in range $10^{-5} – 10^{-10} \text{ M}$). Thus, the rate of exchange of monomers between the bilayer and surrounding solution is slow (minutes to hours). Once formed, the vesicle aggregates cannot be destroyed by dilution, whereas micelles are destroyed. Vesicles, owing to their dimensions, can solubilize a larger number of analyte molecules per aggregate entity compared to micelle systems. In addition, molecules/analyte species may be entrapped within the inner water pool of vesicles for extended periods of time (days and weeks). Of course, one disadvantage of vesicle/liposome systems is that their preparation is more complicated and less convenient compared with that of micelles. In addition, one must be aware of the possibility of aging effects due to vesicle–vesicle fusion, etc.

Several monographs are devoted to the topic of liposomes, their preparation, characterization, and medical-related applications. In addition, several articles discuss, compare and contrast the features of vesicle-organized media relative to surfactant micelles and CDs with respect to their usefulness in luminescence analysis.

### 2.2 Cyclodextrin Systems

CDs (also referred to as cycloamyloses) are naturally occurring macrocyclic oligomers. They consist of six or more linked glycopyranose moieties and are doughnut-shaped molecules. The CDs differ in the number of glucose units they possess, with the designation alpha- ($\alpha$-CD), beta- ($\beta$-CD), and gamma-CD ($\gamma$-CD) containing six, seven, and eight such units, respectively. The internal diameters and depths of the CDs are 4.5–6.0 and 4.5 Å for $\alpha$-CD, 6.0–8.0 and 7.0 Å for $\beta$-CD, and 8.0–10.0 and 7.0 Å for $\gamma$-CD. The interior of the torus of CDs is relatively apolar relative to water and is therefore capable of including a variety of guest analyte molecules. The interior volumes are 176, 346, and 510 Å³ for $\alpha$-, $\beta$-, and $\gamma$-CD, respectively. For comparison, the micellar hydrophobic volume for SDS, CTAC, and Triton X-100 are 21 000, 50 400, and 73 600 Å³, respectively. Also, in contrast to bile salt and surfactant micellar and vesicle aggregate systems, the CDs are chemically and conformationally stable, permanent molecular entities. Thus, CDs are more robust and durable in comparison and can be employed in a variety of solvent systems since there is no monomer $\leftrightarrow$ aggregate equilibrium involved as in the formation of micellar aggregates. These cyclic oligosaccharides are well known to be able to include a wide variety of guest molecules in their toroidal cavity and alter the physicochemical
properties of such guest species. (13,18,160–162) During the past decade, a variety of modified CDs have been prepared, many of which exhibit enhanced (or more selective) binding ability including enantioselective binding. (163–165)

Several monographs provide much more detailed information on CDs along with their properties and applications. (13,160–162,165)

Table 2 compares and contrasts these different organized micelle, vesicle, and CD assembly systems in terms of some of their properties and features. (18,166–168) Additional information on and comparisons among these different membrane mimetic agents can be found in an excellent monograph by Fendler. (18)

### 2.3 Summary of Selected Properties of Organized Assemblies

The ability of organized assemblies to solubilize solutes, to alter their microenvironment and effective concentrations, and hence to affect their reactivities, product distributions, stereochemistries, ionization constants, and redox potentials has been exploited in a number of chemical analysis applications. (9–14,94,125,166)

The influence of the medium upon the energy of electronic states and solvatochromic shifts has been the topic of several reviews. (1–8,167–170) Organized assembly systems solubilize and bind various types of organic molecules in aqueous solutions. Fluorescence probe techniques (see Absorption and Luminescence Probes) have provided much valuable information about the microenvironment of ordered media (i.e. their apparent viscosity, polarity, etc.), which in turn allows conclusions to be made concerning the structure, location, and dynamics of molecules solubilized in such organized systems. (11–8,18,171–176) This section will summarize some of these more important general features, as they pertain to enhancing the performance of analytical fluorescence measurements.

#### 2.3.1 Solubilization Ability

As illustrated in Table 3, the aqueous solubility of sparingly water-soluble organic compounds can be increased by the addition of organized assemblies to the aqueous solution. (42,94,177–185) The solubility of hydrophobic compounds in water can be dramatically enhanced by the addition of a surfactant to

</table>

<sup>a</sup> Coumarin C-120 refers to 4-methyl-7-aminocoumarin and coumarin C-1 refers to 4-methyl-7-dimethylaminocoumarin.

<sup>b</sup> CPC refers to cetylpyridinium chloride.

The uptake of the aqueous solution<sup>21,94,177–203</sup> Such enhanced solubilization is due to the formation of micelles by the surfactant, because below the CMC little increase in solubility is observed, yet above the CMC the increase in solubility is typically directly proportional to the surfactant concentration.<sup>94,178,190</sup> The absolute solubility of a solute in a micellar system depends upon the specific experimental conditions (surfactant concentration, presence and concentration of other additives, pH, temperature, and nature of the solute).<sup>94,192</sup> In addition, the solubilization power of surfactant aggregates depends upon the shape of that micelle entity (spherical, rodlike, etc.), with the solubilization capacity being proportional to the respective micellar volumes.<sup>193</sup>
solute into the micelle can change the physical state of the micelle and result in changes in the physical properties of the system.\(^{94,1}\) As in the situation with the surfactant monomer, the solubilized solute is not rigidly fixed in the micelle. Instead, it can move about within the micelle monomer, the solubilized solute is not rigidly fixed in the micelle and result in changes in the physical properties of the system.\(^{94,1}\)

As illustrated by the data in Table 3, the presence of micelle assemblies can enhance the solubility of sparingly soluble solutes by several orders of magnitude. For some other examples, the solubility of phthalimides increases by approximately an order of magnitude in 0.10 M SDS micellar solutions compared with the solubility in pure water.\(^{195}\) The aqueous solubility of \(\alpha\)-tertiophene is \(<10^{-7}\) M. However, aqueous solutions containing 38 \(\mu\)M \(\alpha\)-tertiophene could be prepared in the presence of surfactant CTAC, dodecyltrimethylammonium chloride (DTAC), SDS, or Triton X-100 micellar media.\(^{196}\) The presence of cationic CTAB micelles increases the solubility of folie acid in water by a factor of 216.\(^{184}\) Most metal ion complexes of oxine (8-hydroxyquinoline) and its derivatives are insoluble in aqueous solution; however, these can be solubilized in surfactant micellar media.\(^{198}\) Cholesterol monohydrate’s solubility in aqueous micellar NaTC is ca. 90 times greater than that in bulk aqueous solution.\(^{199,176}\)

 Likewise, surfactant vesicle/liposome systems can enhance the solubility of organic compounds. For instance, the aqueous solubility of bilirubin-IX\(\alpha\) is \(9 \times 10^{-8}\) M. However, concentrations up to \(1 \times 10^{-3}\) M were prepared in aqueous solutions containing 200 \(\mu\)M PC vesicles.\(^{198}\) Bilirubin’s solubility in the bile salt sodium cholate (NaC) micellar medium was reported as 30 mM.\(^{125,199}\) Although the flavonoid baicalein as well as coomassie brilliant blue dye–CTAB detergent complexes are insoluble in water, they can be solubilized in phospholipid vesicle membrane media.\(^{200,201}\) Nile red is sparingly soluble in water \(<1\ \mu\text{g}\,\text{mL}^{-1}\), but very soluble in aqueous micelle or vesicle solutions and organic solvents.\(^{202}\) Fluorescence spectroscopy has been employed to study the solubilization of ketoconazole and griseofulvin in different bile salt micelles.\(^{203}\)

The presence of CDs also generally increases the solubility of organic compounds in water, but this depends on the solute and the CD.\(^{13,160,161}\) For instance, the solubilities of benzoic and aliphatic carboxylic acids were increased in the presence of \(\alpha\)- and \(\beta\)-CDs, whereas the solubilities of carboxylic acids containing bulky groups were not appreciably affected.\(^{161}\) The solubility of the flavin, lumichrome, and carbazole alkaloids in water increases with an increase in the concentration of \(\beta\)-CD.\(^{204,205}\) The presence of 10 mM \(\beta\)-CD enhanced the aqueous solubility of \(\text{syn}\)-bimanes by ca. 10\%.\(^{206}\) In the presence of 3 mM \(\beta\)-CD, the solubility of lumichrome is threefold greater than in bulk water alone. However, the solubility of hydrophobic molecules in CDs is poor compared with other organized assemblies, such as aqueous micelles, and this factor is considered by some to be a serious disadvantage of CD systems.\(^{207}\) In some cases, analyte-included CD complexes can precipitate from solution, especially from more concentrated stock solutions.\(^{185,208}\) The solubility product and solubility of CD inclusion complex precipitates as well as requirements for formation of such precipitates have been reported.\(^{209,210}\) CDs have been employed in preparation of pharmaceutical formulations not only to enhance solubility, but also to increase the permeation and bioavailability of drugs in biological systems.\(^{211–213}\) However, the utilization of derivatized CDs, which are themselves more water soluble, generally improves their solubilization capacity. For instance, complexation of an indolinonic nitroxide radical with randomly methylated \(\beta\)-CD served to improve not only the nitroxide’s aqueous solubility, but also its photostability.\(^{214}\)

In some situations, organized assemblies have been employed merely for solubilization purposes in fluorescence assays. For example, the surfactant Triton X-100 was employed in the isolation of membrane-bound proteins owing to its ability to disrupt membranes and solubilize proteins without denaturation. The subsequent assay of the protein was achieved by reacting it with fluorescamine and monitoring the FI (excitation and emission wavelengths, \(\lambda_{\text{ex}} = 390\ \text{nm}, \lambda_{\text{em}} = 475\ \text{nm}\)) of the product.\(^{215}\) The presence of the Triton X-100 solubilization agent did not affect the fluorimetric measurements.

A sensitive fluorescent assay for lipase activity utilized egg PC liposomes or a mixed bile salt/liposome system to solubilize the nonfluorescent substrate 4-methylumbelliferyl butyrate.\(^{216}\) Triacylglycerol lipase was incubated in this medium, and after termination of the analytical reaction the FI measured \((\lambda_{\text{ex}} = 365\ \text{nm}, \lambda_{\text{em}} = 450\ \text{nm}\)) of the product. The detection limit of lipolytic activity was \(10\ \mu\text{M}\ h^{-1}\) in the mentioned organized assembly medium.\(^{216}\)

A simple, sensitive, and rapid assay for vitamin \(K_1\) was developed which uses the photo-oxidation of glucose sensitized by vitamin \(K_1\).\(^{217}\) The hydrogen peroxide generated in the photochemical reaction was determined through the iron(II)-catalyzed oxidation of benzoic acid.
to form hydroxybenzoic acid isomers, which fluoresces. The use of Triton X-100 micelles was employed in order to overcome the problem of the poor water solubility of the phylloquinone. In addition, in the absence of TX-100, the ferrous ion is rapidly oxidized to ferric ion, which is unstable in basic aqueous media and slowly precipitates (owing to the formation of the oxide and/or hydroxide salts), which causes signal instability and clogs the flow-injection analysis (FIA) tubing. The presence of the Triton X-100 micellar medium successfully avoids these deleterious effects and problems.\(^{217}\) CTAC micelles were incorporated into a fluorescent method for the simultaneous determination of fat-soluble (vitamins A and E) and water-soluble vitamins \(\text{B}_2, \text{B}_3, \text{and B}_6\)\(^{187}\) (see Vitamins: Fat and Water Soluble, Analysis of). Hence, the solubilization property of organized assemblies allows one to work directly in an aqueous phase without the need for organic or mixed aqueous–organic solvents. In fact, the utilization of organized assembly systems and their solubilization ability can aid analyte sample preservation and storage\(^{218}\) (see Sampling and Sample Preparation in Process Analysis; Sample Preparation Techniques for Elemental Analysis in Aqueous Matrices). Two of the more frequent and serious difficulties encountered when working with real-world samples concern analyte loss due to its adsorption on the surfaces (walls) of the storage container or to its interaction with organic particulate matter or soil sediments (humic materials, bentonite, etc.). The use of surfactant micellar media can obviate both problems. For example, one study found that the presence of Brij-35 surfactant in the sample solution was as effective as 40% (v/v) acetonitrile in preventing loss of polycyclic aromatic compounds (PACs) due to adsorption on the surface of borosilicate glass, white polyethylene, or polytetrafluoroethylene (PTFE) containers.\(^{219,220}\) The addition of nonionic Triton X-114 was also found to enhance PAC recovery during sample preconcentration.\(^{221}\) In a Brij-35-modified procedure for determination of 13 polycyclic aromatic hydrocarbons (PAHs), it was reported that the Brij-35 micellar solutions containing these PAHs were stable for at least 24 h, except for those of naphthalene, anthracene, and acenaphthene, whose FI decreased ca. 15, 17, and 12%, respectively, over 24 h.\(^{222}\) Enhanced stability of PAHs in the presence of the nonionic surfactant polyoxyethylene-10-lauryl ethers has also been reported.\(^{223}\) With biological/clinical samples, it was noted that the addition of SDS was effective in preventing the sticking of protein to the tubes and pipet tips, leading to more reproducible results in a protein fluorescence quantitation based upon reaction with \(o\)-phthalaldehyde.\(^{224}\) The nonionic surfactant polyethylene (20) sorbitan monolaurate was demonstrated to prevent DNA adhesion to the surface of the containers.\(^{225}\) Likewise, the use of micellar sodium dodecylbenzenesulfonate (SDDS) prevented the adsorption of different metal–porphine chelates on glassware surfaces.\(^{226}\)

It has been reported that the presence of CDs can prevent (or reverse) the effects of sample adsorption of analytes to the walls of the container. For example, addition of \(\beta\)-CD led to the dissolution of pyrene that had been adsorbed on the walls of the glassware.\(^{227}\) Addition of solutions of CDs also successfully sequestered (redissolved) organic molecules from the walls of glass tubes on which they had been deposited into the aqueous solutions.\(^{228}\) Memory effects due to adsorption of metal ions, such as \(\text{Eu}^{3+}\), on the walls of glass containers during storage of stock solutions have been reported.\(^{229}\) Such effects might be diminished or eliminated if surfactant micelles or CDs were added and present in the stock solution.

### 2.3.2 Solute Incorporation and Binding to the Organized Assembly

Solute binding to organized assemblies has resulted in widespread applications of such systems in pharmaceutical chemistry, catalysis, chemical analysis and separation science, and food technology, among others.\(^{9–13,18,94,160,230}\)

The binding association of a solute molecule with a micelle may be divided into several stages corresponding to the different sites of possible interaction: the bulk solution, the micelle outer surface region, and the more hydrophobic micelle interior (refer to possible binding sites as depicted in Figure 1). In the initial stage, the rate of interaction is the bulk solution encounter rate, which is typically near the diffusion-controlled limit (i.e. ca. \(3 \times 10^6 \text{dm}^3 \text{mol}^{-1} \text{s}^{-1}\)),\(^{178,231–233}\) particularly when the solute and micelle species are of opposite charge. Solute protonation or deprotonation may occur in the second step since the micelle surface region pH is typically different, sometimes by ca. 2 pH units, from that of the bulk aqueous solution phase.\(^{233,234}\) The rate of proton transfer in micelle systems is also typically diffusion controlled, so that this is not ordinarily the rate-determining step.\(^{233,235}\) The final stage of incorporation represents the complex set of interactions resulting from hydrophobic and/or electrostatic forces as the solute occupies its preferential averaged-binding site, either in the micellar core or surface regions or in some intermediate position. This last step is typically the rate-limiting one for solute incorporation. For instance, when neutral dye molecules, such as methyl red (MR), methyl orange (MO), or pyridine-2-azo-\(p\)-dimethylaniline (PADA), are incorporated into SDS or CTAB micelles, the rate constants are in the
Solute incorporation rate constants (entrance rates) are typically in the range of $10^8 \text{--} 10^{10}$ M$^{-1}$ s$^{-1}$, while the solute rate constants for exit from the micelle (exit rates) are in the range $10^2 \text{--} 10^8$ s$^{-1}$ depending upon the specific solute–surfactant micelle combination. Since the entrance rate constants are generally near diffusion controlled, it is the exit rate constant that typically dictates the magnitude of the degree of solute binding to the micelle.

Solute complexation with CDs is also a dynamic process. The entry and exit rate constants for the complexation of naphthylethanols with β-CD have been determined. Rate constants for entry and exit of guest molecules into such CD hosts are typically of the order of $10^8 \text{--} 10^9$ M$^{-1}$ s$^{-1}$ and $10^3 \text{--} 10^7$ s$^{-1}$, respectively (for 1 : 1 complexation stoichiometry). To a first approximation, the strength of binding correlates with the fit of the solute molecule in the CD cavity. The interior of the doughnut-shaped CD molecule is lined with oxygen and CH groups, providing a relatively hydrophobic binding site for molecules of appropriate size that can fit the particular CD’s cavity. One exterior side of the torus contains the primary hydroxyl groups, while the other side contains a number of secondary hydroxyl groups characterized by the glucose moieties. Thus, these hydroxyl groups offer hydrogen-bonding sites to the portion of secondary hydroxyl groups on the C-2 and C-3 atoms of the glucose moieties. These hydroxyl groups offer hydrogen-bonding sites to the portion of a solute molecule that possesses an appropriate hydrogen-bonding moiety. Since CDs (and also the bile salt micelles) are chiral entities, differences can be observed in the binding constants for an enantiomeric pair of analytes for these two organized assembly systems.

In synthetic surfactant vesicle or natural liposome aggregate systems, there are several possible analyte binding sites that exhibit a range of polarities. At the water-pool–head-group interfacial regions, the sites are relatively hydrophilic, whereas more hydrophobic (and ordered) sites are available within the hydrocarbon interior of the bilayers. Of course, between these two extremes lie sites of intermediate hydrophobicity. Figure 2 depicts some of these potential binding sites for a liposome system, illustrating the binding of the relatively polar benzyl alcohol and less polar n-propylbenzene molecules to an egg yolk PC SUV. Consequently, it should not be surprising that, depending on the luminescent probe employed and its specific binding site, a number of possibilities for interaction of solutes of differing hydrophobicity (or polarity) within the vesicle interior exist.

The fluorescence technique has proven to be a very useful means by which to determine the binding constants for equilibrium interaction of an analyte, $A$, with a particular organized assembly, $OA$, system Equation (1):$^{11,13,173,244-246}$

$$K_B = \frac{[A_W]}{[A_{OA}]}(OA)$$

$$A_W + OA \rightleftharpoons A_{OA}$$  (1)

The equilibrium or binding constant, $K_B$ (M$^{-1}$), is given by Equation (2):

Figure 2 Artistic representation showing the bilayer structure of an entire small unilamellar vesicle (liposome) of egg yolk PC, along with an upper expanded view of possible solute binding sites. A more polar solute, such as benzyl alcohol, would be located near the surface phospho head group areas, whereas the less polar n-propylbenzene prefers to bind to the more hydrophobic interior region. (Adapted with permission from E. Okamura, M. Nakahara, J. Phys. Chem., 103, 3505–3509 (1999). Copyright 1999, American Chemical Society.)
ELECTRONIC ABSORPTION AND LUMINESCENCE

where \([A_W]\) and \([A_{OA}]\) denote, respectively, the analyte substrate molar concentration in the aqueous and organized assembly phases, and \([OA]\) is the concentration of the organized assembly under consideration. For micellar systems, the concentration of micellized surfactant is equal to the total surfactant concentration minus that surfactant’s CMC. For micellar media, this solute–micelle binding constant, \(K_B\), can be related to the partition (or distribution) coefficient, \(P\), for distribution of the solute between the micellar and bulk aqueous phases, by Equation (3):

\[
K_B = (P - 1)v
\]  

(3)

where \(v\) is the partial molar volume of the surfactant.\(^{12, 248, 250}\)

The literature contains a plethora of data regarding the interaction and binding of solute (analyte) species to organized assembly systems.\(^{249–317}\) Some representative data (in the form of binding constants or partition coefficients) for the interaction of ions and organic species with different organized media is presented in Table 4. As can be observed, the same analyte can bind to greatly differing extents to different organized assembly systems. Orders of magnitude differences in binding constants can exist for the same general type of organized assembly system. Solute binding constants and residence times in aqueous micelles are of the order of \(10^3 – 10^6\) M\(^{-1}\) and \(10^3 – 10^5\) s\(^{-1}\), respectively.\(^{18}\) For example, the binding of pyrene to different surfactant/bile salt micelles ranges from ca. \(1.5 \times 10^5\) M\(^{-1}\) for NaC to \(1.0 \times 10^7\) M\(^{-1}\) for

</table>
binding to CTAB micelles (Table 4). A comprehensive compilation of solute–micelle binding constants (partition coefficients) is available.\(^{(318)}\)

In the case of micellar media, linear solvation free energy relationships of the form shown in Equation (4) have been reported:

\[
\log K_B = c + a \sum \alpha + b \sum \beta + s \pi_2 + r R_2 + v \left( \frac{V_x}{100} \right)
\]

in which the binding of solutes to a specific surfactant micelle is related to the medium-independent parameters for solute hydrogen bond acidity \(\sum \alpha\) and basicity \(\sum \beta\), excess molar refraction \(R_2\), dipolarity \(\pi_2\), and volume \(V_x\).\(^{(255)}\) For the cationic surfactants DTAB and CTAB, nonionic surfactant Brij-35, and anionic SDS, solute incorporation and binding to the micelle is dominated by the \(V_x\) term (positive, reflecting the hydrophobic effect) and the \(\sum \beta\) terms (negative, implying that bulk water is a better hydrogen-bond donor than the micellar solubilization site).\(^{(255)}\) The contributions of \(\sum \alpha\) and \(R_2\), although smaller, were reported to vary in a chemically satisfying manner with the surfactant charge and structure.\(^{(255)}\) Such linear salvation free energy relationship (LSER) relationships allow the determination of the relative importance of these factors in binding to a specific surfactant micelle and also allow the estimation of the actual solute binding constant for a specific surfactant micelle provided that the solute’s

\(^a\) \(P\) refers to the partition (or distribution) coefficient, with values given in parentheses.

\(^b\) Refers to tris(2,2′-bipyridinium)ruthenium(II) cation.

\(^c\) Refers to 1-anilonaphthalene-8-sulfonate.

\(^d\) Refers to egg PC.

\(^e\) Refers to 3,3-dimethyl-2-phenyl-3\(^{1}\)H-indole.

DPH, 1,6-diphenyl-1,3,5-hexatriene; DTAB, dodecyltrimethylammonium bromide; DMA, dimethylaniline; SB-12, sulfobetain-12; phen, 1,10-phenanthroline; ANS, 8-anilino-1-naphthalenesulfonate; MB, methylene blue; TDSS, sodium tetradecyl sulfate.
required parameters are known. Such an approach should also be applicable to synthetic surfactant vesicle or natural liposome aggregate systems. A similar approach utilizing the transition energy of fluorescent probes in CTAB, SDS, and Triton X-100 was conducted, and the aforementioned solvatochromic parameters determined for these three micellar systems. However, the values were determined using a rather limited number of probe molecules.

Table 4 also includes solute–CD binding constants for formation of 1 : 1 inclusion complexes. Several monographs and reviews summarize methods utilized to determine solute–CD binding constants and also provide binding constant data for a wide range of solutes. On the basis of the examination of 569 such complex systems, Equation (5) was found to provide reasonable estimates of the magnitude of the CD binding interaction:

\[
\log K_B = -1.74 - [Z] + 0.032(\Delta A) \tag{5}
\]

where \([Z]\) incorporates solvent–solute (solvation) and solute–solute interactions and \(\Delta A\) is the decrease in nonpolar surface area (in \(\text{Å}^2\) per molecule) of the substrate that is exposed to the solvent upon binding to the CD cavity. A phenomenological theory has been proposed for estimation/prediction of the magnitude of the binding constants for formation of 1 : 1 \(\alpha\)-CD–solute inclusion complexes in aqueous solution at 25°C.

In addition to the selected data presented in Table 4, binding constants for the inclusion complexation of 56 mono- and 1,4-disubstituted benzenes with \(\alpha\)- and \(\beta\)-CD have been reported. Binding constants for the interaction of naphthalene and some of its mono- and dimethyl derivatives with \(\alpha\)-, \(\beta\)-, and \(\gamma\)-CD are available. The binding constants of 13 flavonols to \(\beta\)-CD under acidic and basic conditions have been reported. It is evident from the data in Table 4 that the three different CDs can have large differences in the magnitude of the binding constant with respect to the same solute (as a consequence of the steric requirements and size of the solute in relation to the size of the specific CD cavity). It is important to note that the same solute can bind differently (positionally) to the three CDs. For instance, methyl salicylate binds to \(\alpha\)- and \(\beta\)-CD in different geometries. In the former case it was postulated that the ester and hydroxyl groups were buried in the interior cavity, whereas in the latter case the phenyl end of the methyl salicylate molecule binds in the cavity. The magnitude of solute–CD binding constants typically decreases with an increase in temperature. For instance, the binding constant for interaction of 1-naphthyl acetate with \(\beta\)-CD is 463 M\(^{-1}\) at 15°C and only 134 M\(^{-1}\) at 40°C.

The CD : solute stoichiometry and magnitude of binding interaction can also be impacted by the presence of other organic additives, depending on the additive’s hydrophobicity and spatial volume. For example, it was noted that the binding constant for interaction of 1-naphthol with \(\beta\)-CD decreased if methanol or ethanol was added to the aqueous solution. However, Nakajima demonstrated an increased binding constant of pyrene and \(\beta\)-CD in the presence of ethanol. Warner et al. have also reported that the presence of small amounts of other additives can impact the magnitude of CD–aromatic solute binding constants. For example, the addition of 1.0% of alcohol greatly enhances the binding of pyrene to CDs. Dramatic enhancements of fluorescence quantum yield with coumarin laser dyes have been observed upon inclusion by \(\beta\)-CD in aqueous solution, but only when small amounts of organic cosolvents were also included. This was interpreted in terms of the fact that the small organic molecules displace water (which has a pronounced fluorescence quenching ability) from the CD cavity and act as space fillers to enhance binding. Likewise, addition of cyclohexanol as cosolvent to aqueous solutions of \(\gamma\)-CD containing 2-naphthoxyacetic acid (2-NAA) resulted in an increase in the FI of 2-NAA. As 1-butanol is added to aqueous solution containing the \(\gamma\)-CD–pyrene 1:2 complex, it displaces one of the pyrene molecules from the CD cavity to form the 1 : 1 CD–pyrene–butanol complex. The binding interaction between sodium salicylate and \(\beta\)-CD was also increased owing to the presence of various alcohols. However, in this instance, the addition of the alcohol to the system resulted in a decrease in the FI observed from salicylate.

The nature of the bulk solvent as well as charge on the CD (or solute) also impacts their solute binding ability. For instance, the interaction of ketocyanine dyes with \(\beta\)-CD dissolved in aqueous and dimethylformamide (DMF) as bulk solvent is different. The equilibrium binding constants were found to be greater for ketocyanine binding to \(\beta\)-CD that was dissolved in the nonaqueous media. An investigation of the binding of piroxicam to neutral \(\beta\)-CD and a charged \(\beta\)-CD revealed that the charged form interacted more strongly with this analyte. The neutral form of the drug celecoxib was found to bind to \(\beta\)-CD approximately four times better compared to its ionized form.

In the case of CDs, buffer and salt components employed to adjust the pH and/or ionic strength influence the equilibrium constant for the particular CD–solute inclusion complexation process. For instance, the binding constant for interaction of 3-hydroxy-2-naphthoic acid with \(\beta\)-CD at pH 5 and 25°C ranged from 264 M\(^{-1}\) in the presence of sodium perchlorate to 1260 M\(^{-1}\) in...
the presence of sodium chloride (ionic strength 0.1 M) (the binding constant in the absence of any salt was 1083 M$^{-1}$). Thus, differences in the strength of analyte binding to CDs could also impact and influence the magnitude of fluorescence observed. Hence it is important to compare only similar systems and, in analytical measurements, to ensure that such variables are held constant.

Likewise, the addition of additives can alter the FI of analytes bound to vesicle/liposome assemblies. For example, the FI of 1,6-diphenyl-1,3,5-hexatriene (DPH) in DPPC vesicles is reduced by over 50% due to the presence of added ethanol. The ethanol causes the DPPC aggregates to undergo the L$_{α}$ to L$_{β}$I phase transition which alters the location and binding environment of the DPH solute with a resultant decreased fluorescence efficiency. Alternatively, surfactants can be added to produce similar effects. Alterations in temperature can also have dramatic effects on the magnitude of solute partitioning into vesicle/liposome systems. Differences in the vesicle size (which varies with the preparation method employed) can affect solute binding. For instance, the magnitude of the binding constants for interaction of n-heptanethiol with DODAC vesicles were 500, 1200, and 2800 M$^{-1}$ for vesicles whose hydrodynamic diameters (size) were 2850, 520, and 220 Å, respectively. Hence all of these factors that influence analyte binding to vesicle/liposome aggregate systems can in turn alter the maximum fluorescence emission intensity observed from those solutes as well.

With respect to solute binding to a particular organized assembly, it should be recognized that there is a distribution of locations instead of a unique specific binding location in the assembly (i.e. a heterogeneity of binding sites exists, each site being characterized by a different microenvironment). In addition, there is the possibility of organized assembly heterogeneity (a distribution of micelles or vesicles of different aggregation numbers, etc.). Ordered lipid systems are thought to be heterogeneous in the sense that fluorescent solutes, when embedded in such ordered lipid media, are situated within different sites of different ordering and mobilities.

Hence this multitude of possible interactions during the excited-state lifetime of the solute in such an organized system results in a multitude of deactivation channels of the excited state, leading to distributions in such fluorescence properties as lifetimes, quantum yields, etc. Huang and Bright noted that for micellar media, there could be several contributions to such observed distributions including (i) water gradients, (ii) micelle polydispersity, and (iii) compositional diversity within the micelles.

All of the binding constant data reported for the CD–solute combinations in Table 4 were for the 1 : 1 complexes (one solute molecule bound per CD molecule). However, in some situations, higher-order complexation can occur, with 1 : 2, 2 : 1 or 2 : 2 CD:solute complex stoichiometry being reported. Coumarin 153 forms both 1 : 1 and 1 : 2 complexes with methylated β-CD. The size of the particular CD cavity serves to impose possible steric restrictions with respect to the number of analyte molecules which can be bound. For example, the larger-diameter γ-CD can accommodate two pyrene molecules, whereas in the cases of binding to α- or β-CD, only one pyrene is bound. Such results indicate that an important factor in solute binding to CDs in aqueous solutions is the size of the analyte in relation to the cavity dimensions of the particular CD.

In the case of micelles (or vesicle systems), an useful means to assess the degree of solute occupancy is to assume that the analytes distribute among the micelle/vesicle aggregates according to Poisson statistics. The probability of a micelle containing x analyte molecules is given by Equation (6):

$$P(x) = \mu^x e^{-\mu} \frac{x!}{x!}$$

where $\mu$ is the stoichiometric mean number of analyte molecules per micelle (i.e. [analyte]/[micelle]) and $P(x)$ the probability of a micelle with an occupation of x analyte molecules (for a brief discussion of the distribution of solubilized molecules among micelles, see Miller). The concentration of micelles [micelles] is given by Equation (7):

$$[\text{micelle}] = \frac{C - \text{CMC}}{N}$$

where $C$ is the surfactant concentration and $N$ is the micelle aggregation number. As an example, for a solution of an analyte whose concentration is 1 mM in a 0.10 M SDS micelle medium, the average number of analyte molecules per SDS micelle, $\mu$, would equal 0.6 (assuming an aggregation number of 60 for SDS). For this example, $P(0) = 0.549$ (54.9% of the micelles contain no analyte molecule) and $P(1) = 0.329$ (32.9% of the SDS micelles contain one analyte molecule), and 12.2% of the micelles would contain two or more analyte molecules. By contrast, if the analyte concentration is only 1.0 × 10$^{-5}$ M, then only 0.3% of the occupied micelles (0.6%) would contain two or more analyte molecules.

As another example, for a micelle concentration of 1.0 mM and an oxygen concentration of ca. 0.10 mM, $\langle O_2 \rangle = 0.1$; thus 90% of the micelles will be free of oxygen. As a consequence, analyte molecules bound to the micelles would be “protected” from oxygen quenching. Consequently, manipulation of the concentration of micelles in relation to that of the analyte...
(or analytical reagents/impurities present) is possible so as to prevent multiple analyte/solute/impurity occupation of the micelles. At any given analyte concentration, an increase of concentration of micelles will serve to decrease $\mu$. A relatively high surfactant micelle to analyte concentration ratio will serve to ensure that the probability of any one micelle containing two or more analyte (or analyte–solute or analyte–impurity, etc.) molecules is very low. This in turn eliminates (or greatly reduces) the possibility of formation of the dimeric form of the analyte molecule (which typically are not or weakly luminescent) or diminishes other solute/impurity quenching of that analyte.

In addition, for situations in which both analyte and quencher bind to the micellar aggregate, the quenching efficiency typically decreases with increasing surfactant concentration.\(^{(266)}\) This is a consequence of the fact that increasing surfactant concentrations result in formation of a greater number of micelle aggregate species; thus, the probability that any one micelle has both the analyte and quencher bound to it decreases. Thus, impurity quenching (of analytes) can be suppressed in micellar solutions provided that the fluorescent analyte and the impurity molecules are likely to be solubilized in different micelles. In fact, in one report it was noted that the fluorescence quantum yield for 9,10-dimethylanthracene in ethanol was lower compared to that in the literature and that this was likely due to impurities present in the chemical.\(^{(529)}\) However, in micellar solutions, the anticipated value was observed despite the presence of that impurity. This clearly demonstrates that impurity quenching can be suppressed in micellar solutions.

### 2.3.3 Effect of Organized Assembly Systems upon the Reaction Rate and Path

Aqueous organized assembly systems often induce changes in a wide variety of ground- and excited-state reactions. Reactions and the position of chemical equilibrium in such systems often proceed in a manner very different from that observed in homogeneous bulk solvents owing to the altered microenvironment and concentration effects in the organized medium.\(^{(7,18,161,350,351)}\) It is well known that surfactant micellar systems or CDs can impact (either accelerate or inhibit) many types of chemical reactions.\(^{(18,94,140,161,350–353)}\) An excellent recent review article discusses reactions in micellar systems\(^{(350)}\) and an exhaustive compilation of altered reactivities in different ordered assembly systems is provided in monographs by Fendler.\(^{(18,353)}\) A model (pseudophase ion exchange (PPIE)) has been developed for ionic micellar solutions, which is capable of describing and predicting most ionic micellar effects on reaction rate and equilibria over a wide range of experimental conditions (pH, detergent, added salt, etc.).\(^{(324)}\) A review article summarizes and discusses the use of CDs to mediate a wide range of different types of organic reactions.\(^{(355)}\)

As examples of ordered media effects, reactions involving the cleavage of phenyl esters, decarboxylation of cyanoacetates, and oxidation of $\alpha$-hydroxyketones were accelerated by factors of 300, 44.2, and 3.3, respectively, in the presence of CDs compared with that in their absence.\(^{(161)}\) Decarboxylation reactions were also enhanced in the presence of micellar systems. For instance, the presence of CTAB, Triton X-100, and SDS enhanced the rate of decarboxylation of 5-amino-1,3,4-thiadiazole-2-carboxylic acid by factors of 5.0, 5.7, and 1.3, respectively.\(^{(18)}\) Cationic CTAX micelles caused an increase in the rates of reduction of the carbonyl group of steroids by factors of 2.2–7.8, depending upon the steroid’s structure.\(^{(94)}\) In addition to alteration of the rates of reactions, the product distribution (including stereochemistry) can be affected by the presence of organized assemblies such as CDs or micelles.\(^{(94,161)}\) The photodecarboxylation reaction of ketoprofen occurs with a decreased rate in the presence of $\beta$-CD compared to that in aqueous solution. Also, in the $\beta$-CD medium, an additional photoreaction was observed.

Review articles discuss the factors that affect the kinetics of photoreactions in organized assemblies and the topics of photochemistry in surfactant solutions and the fate of excited-state probes in micelles.\(^{(2–8,167–169,356–360)}\)

The type and concentration of organized media can also have a profound effect upon different photochemical processes.\(^{(6,7,94)}\) For instance, the quantum yield of trans $\rightarrow$ cis photoisomerization of (dibutylamino)stilbazolium butanesulfonate was found to be almost 2 orders of magnitude greater in micelle and vesicle ordered media compared to that in bulk water.\(^{(32)}\) In contrast, the yield for the trans $\rightarrow$ cis photoisomerization of azobenzene in the presence of CDs was roughly only half of that observed in 80:20 (v/v) water/methanol solution.\(^{(356)}\) The rate constants for hydrolysis of cytotoxic pyronins is altered compared to that observed in a bulk alkaline medium.\(^{(357)}\) For example, the presence of cationic CTAB micelles resulted in a threefold higher rate constant compared to that in aqueous solution, whereas the hydrolysis reaction was completely inhibited by anionic SDS micelles.

Vesicle/liposome systems can also alter reactivity. The second-order rate constants for the alkaline hydrolysis of $p$-nitrophenyl octanoate in the presence of DODAC or DODAB surfactant vesicle systems were 28–61 times larger than the rate observed in water in the absence of the amphiphile at the same pH.\(^{(336)}\) The bimolecular
rate constant for the photooxidation reaction of 1,3-diphenylisobenzofuran with singlet molecular oxygen in the presence of zinc(II) phthalocyanine is roughly 2 orders of magnitude smaller in the presence of DPPC liposomes compared with that in ethanol solution.\(^{[361]}\)

The rate and quantum yield of electron exchange between excited pyrene, P and dimethylaniline (DMA) (Equation 8):

\[
\text{DMA} + P^* \rightarrow P^- + \text{DMA}^+ \quad (8)
\]

to yield the pyrene anion and DMA cation has been examined in different media.\(^{[362]}\) A continual decrease in the yield of the pyrene anion (ion yield of 1.0 in the presence of aqueous CTAB micelles) is observed on going from aqueous micelle to aqueous vesicle to swollen micelle to microemulsion systems, with no yield of ions observed in reverse micelles.\(^{[362]}\)

The presence of β-CD reduced the initial rate of product formation in the photohydroxylation of 3-nitroanisole compared to that observed in homogeneous aqueous buffer solution.\(^{[259]}\) Many organic molecules exhibit a greater degree of photostability in organized assembly media compared to the general behavior observed in organic solvents.\(^{[1–8,18,42,214]}\) The observed rate constant for the second-order decay of mesitylthiyl radicals was 3000 times less in a 0.05 M SDS micellar medium than that observed in heptane.\(^{[363]}\)

Quenching of excited states of molecules can be dramatically altered in the presence of organized media. Depending on the nature (size, hydrophobicity, or charge type if an ion) of the quencher and luminescent molecules in relation to the type (micelle, CD, vesicle, etc.), nature (neutral or ionic), and concentration of the organized media, either decreases or increases in quenching can be observed. In aerated solutions, the fluorescence lifetime of pyrene in pure water is shorter (126 ns) than in aqueous solutions of CTAC or SDS micelles (157–158 ns).\(^{[364]}\) This was initially rationalized in terms of either a (i) lesser solubility of oxygen in the micelle relative to water, (ii) rate constant for oxygen-quenching of solubilized pyrene slower than diffusion controlled in bulk solution, or (iii) quenching of pyrene fluorescence by water.\(^{[364]}\) Reasons (i) and (iii) were subsequently ruled out.

The main factor responsible for enhanced lifetimes in organized media thus appears to be decreased quenching constants. For example, the excited state of pyrene is quenched by oxygen molecules in bulk solvents. The bimolecular quenching rate constant is \(1.1 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}\) in aqueous solution.\(^{[362]}\) However, it is about an order of magnitude less in the presence of β-CD (\(1.2 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}\)). In the presence of a mixed organized system containing either SDS or CTAB and the β-CD, the quenching rate constant is further reduced to \(6.0 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}\).\(^{[362]}\) These results were rationalized as follows: The pyrene can bind to the cavity of the β-CD molecule, wherein it is somewhat protected from quenching by other molecules, such as oxygen, following its excitation. The addition of either SDS or CTAB results in the surfactant molecule also binding to the CD cavity, which leads to a more hydrophobic microenvironment for pyrene in addition to a greater binding constant and greater protection from quencher molecules. Similar results concerning resistance to oxygen-quenching of fluorescence for other organic solutes bound to organized assemblies have been reported.\(^{[42]}\) Pyrene is also considerably protected from oxygen if present in DODAC vesicles.\(^{[146]}\) In a comparative study of several micellar systems, the effectiveness of the protection of pyrene from oxygen-quenching (as given by the lifetimes of excited pyrene) was Brij-35 > SDS > surface-active crown ether decyl-18-crown-6.\(^{[365]}\) The conclusions of another study indicated that nonionic surfactant micelles were more effective in protecting excited states of organic molecules from oxygen-quenching compared to ionic micelles.\(^{[366]}\)

Likewise, 1 to 2 orders of magnitude reductions in the bimolecular quenching rate constants were observed for pyrene with the quenchers nitromethane, thallium(I) cation, copper(II) cation, and methyl viologen cation in the presence of these organized assemblies.\(^{[364]}\) Thus, via the use of CDs, with or without added surfactants, it is possible to shield pyrene to various degrees from quenching interactions due to external species.\(^{[207]}\) A nearly fourfold decrease in the quenching efficiency of iodide ion toward 2-naphthol was observed when the naphthol was bound to α-CD.\(^{[324]}\) The presence of β-CD, which served to bind the methyl-2-aminobenzoate (MAB) solute, dramatically protected MAB against quenching by iodate ion. The fluorescence quenching of pyrene by N,N-DMA was diminished by a factor of ca. 7.5 in the presence of β-CD compared with that observed in the 50 : 50 (v/v) dimethylsulfoxide–water bulk solvent in its absence.\(^{[283]}\) Therefore, the use of organized media can minimize or obviate detrimental analyte–solute (or solvent) interactions that otherwise might lead to quenching deactivation of the analyte’s excited state.\(^{[209]}\)

However, if both fluorescent solute and quencher molecules are of appropriate size so that they both bond to one CD cavity, then the quenching interaction can be enhanced. For example, in the presence of β-CD, the fluorescence quenching of naphthalene, 1-methylnaphthalene, and acenaphthene by trimethylamine was greater by factors of 17, 91, and 280, respectively, compared to that observed in water at 25 °C.\(^{[367]}\)

Metal cations are attracted as counterions to the surface of anionic micelles or vesicles and act as more...
efficient quenchers, whereas anionic species are repelled and ineffective. The opposite would be true for cationic micelles or vesicles for which anions would be more efficient quenchers.\(^\text{347}\) Hence, the use of appropriate micellar media can be utilized to achieve some selectivity against charged quenchers. For example, metal (or other) cationic species are repelled from cationic micelles and their quenching of micellar-bound solutes is thus ineffective. Likewise, anionic species would be repelled from anionic micelles and hence bind solutes protected from such quenchers. Consequently, through judicious choice of micelle (or other organized media), charge type (and concentration) in relation to the analyte, and quencher molecules, it is possible to either decrease or increase the quenching efficiency as desired.

The quenching effects of neutral species can also be diminished when luminescent species are bound to micelle systems. For example, the quenching of several aminobenzoic acid derivatives of aminoacylmonomethylamides by acrylamide in pH 7.4 phosphate buffer was decreased roughly by a factor of two in the presence of SDS micelles.\(^\text{368}\) The lowering in quenching indicated a diminution in the rate of collisions between the aminoacylmonomethylamide compounds and the quencher acrylamide. Likewise, the quenching effects of iodide ion toward lumichrome was decreased about fourfold in the presence of \(\beta\)-CD.\(^\text{204}\)

The utilization of organized media for examination of the mechanism of resonance energy transfer has been the focus of many studies. This is due to the importance of such energy transfer in solar energy conversions, photosynthesis, etc. The addition of different organized assemblies has been shown to enhance the efficiency of such energy transfer steps in a number of systems. For instance, efficient energy transfer from the excited state of acridine orange-10-dodecyl bromide (AOD) to methylene blue (MB) has been observed in the presence of SDS micelles.\(^\text{369}\) In contrast, only very little sensitized fluorescence of MB was observed in ethanol as the bulk solvent. Enhancement of the efficiency of energy transfer is possible if the particular organized assembly binds the two species involved so that they are in close proximity. For some systems, it has been shown that vesicle or liposome systems are superior to micelles in this regard. The energy transfer from a donor oxacanine dye molecule to the acceptor thiacyanine dye is 20–100 times more efficient in a cationic vesicle system than in CTAB micelles.\(^\text{1148}\)

The rate of energy transfer from excited \(\text{Tb(pdc)}_3\)^{3−} (pyridine-2,6-dicarboxylate, pdc) to \(\text{Ln(pdc)}_3\)^{3−} is very slow in bulk aqueous solution; however, association of these complex ions with CTAB results in rapid and efficient energy transfer.\(^\text{370}\) The apparent second-order rate constant of energy transfer from 2-acetylnaphthalene to europium(III) ions in SDS micelles is 1 to 2 orders of magnitude larger than the value in homogeneous solution in the absence of SDS, depending upon the specific SDS and Eu(III) concentrations.\(^\text{371}\)

In addition, enzyme-generated triplet species can transfer their energy to suitable acceptors and elicit sensitized emission in organized assemblies. For instance, the electronically excited state generated during the peroxidase-catalyzed aerobic oxidation of appropriate substrates efficiently led to fluorescence emission from acceptors like 9,10-dibromoanthracene or chlorophyll solubilized in CTAB, SDS, and Triton X-100 or Brij-35 micellar media.\(^\text{372}\) It was noted that "micelle-solubilized chlorophyll is an excellent detector of enzyme-generated triplet carbonyl species and the use of micelles make it possible to extend (this approach to study) other photobiologically important yet water-insoluble acceptors".\(^\text{372}\)

Hence it is possible to exploit such unique kinetic effects due to the presence of appropriate organized assembly systems in order to manipulate the rates of reaction for the purpose of enhancing the fluorescence performance; that is, the use of ordered media can catalyze otherwise slow analytical fluorescent derivatization reactions. Alternatively, one can employ such organized systems to inhibit or slow down undesired side or decomposition reactions in order to stabilize the desired fluorescent species.

For example, in a fluorescence assay for cyanide ion based on its reaction with 1,4-naphthaquinone-2-sulfonic acid to form a fluorescent product, the reaction time in the presence of CTAB micelles is only ca. 5 min compared to a reaction time of roughly 90 min in its absence.\(^\text{373}\) The rate of phenolic oxidative coupling of morphone and related opiates to yield fluorescent products, utilized for postcolumn high-performance liquid chromatography (HPLC) detection, was increased in the presence of the nonionic surfactant Triton X-100.\(^\text{374}\) In addition, the micellar medium protected the fluorescent product from further oxidation. The presence of the micellar system thus improved the stability of the system and detection limits possible relative to that observed in bulk solvent with no surfactant present. There are also other examples of micellar catalysis to speed up fluorescent reactions. In a method for determination of laccase activity, the apparent rate of oxidation of \(o\)-phenylenediame catalyzed by laccase was enhanced by Brij-35 micelles.\(^\text{375}\) The detection limit was 0.07 U L\(^{-1}\) laccase. The fluorescence reaction between \(n\)-(4′-hydroxyphenyl)-\(N\)-(4-methylquinolinyl)amine, hydrogen peroxide, and cobalt(II) was remarkably enhanced in the presence of cationic surfactant media.\(^\text{376}\) The fluorescence output was about five times greater in the presence of trimethylstearylammonium chloride (STAC) than in its absence. This reaction was employed to determine
hydrogen peroxide in the 0–250 ng mL⁻¹ concentration range. Brij-35 was found to be effective in increasing the rate (roughly sixfold) of the hemin-catalyzed fluorogenic reaction between hydrogen peroxide and N,N′-dicyanomethyl-α-phenylenediamine. The subsequent method for peroxide was more sensitive (by a factor of ca. 5) in the surfactant medium compared to that in aqueous solution in absence of the Brij-35.

Thiols react with 4-nitro-N-n-butyl-1,8-naphthalimide (4-NBN) to form highly fluorescent products that can be employed for the fluorimetric determination of thiols. The rate of this reaction was greatly enhanced (by a factor of ca. 10⁵) by the presence of cationic CTAC micelles. This increased rate was attributed to the micellar concentration of the reactants and the micellar effect on the extent of the acid–base ionization that generates the reactive thiolate anion which is the nucleophile.

A very popular fluorimetric method for the determination of primary amino compounds is based on their reaction with o-phthalaldehyde in the presence of thiols (such as 2-mercaptoethanol) under basic conditions to form the fluorescent 1-(2′-hydroxyethylthio)-2-alkylisoindole product. The isoindole product formed from many analytes is unstable owing to subsequent decomposition and oxidative reactions. The presence of different micellar and CD organized media can slow such undesired reactions involving the fluorophore. For an overview of the effect of different CD media upon Roth’s method and the fluorescence output from over 45 different aromatic organic compounds, the reader is referred to Frankewich et al.

### 2.3.4 Organized Assembly Effects upon Chemical Equilibrium

Surfactant micelles and vesicles as well as CD media can shift the position of ground-state chemical equilibria. Perhaps the most important and frequent analytical application of such equilibrium shift media has been to alter the position of acid–base equilibrium. Acid–base ionization constants (and other equilibrium constants) can be altered, some by several orders of magnitude, in the presence of organized assemblies compared to those observed in bulk aqueous solution (selected data presented in Table 5). A quantitative method for the evaluation of the influence of surfactant micellar media upon the protolytic equilibrium of various organic reagents has been published. Micelle-induced pKᵣ shifts are due to “medium” (altered microenvironment) and electrostatic effects. Interfacial water is known to be less polar than bulk water and is akin to an electrolyte salt solution (the ionic strength in the Stern layer of ionic surfactant micelles can be in the range 1.0–3.0 M). The degree of dissociation of the charged aliphatic amino group of tetracaine as a function of pH in the absence and presence of surfactant-forming micelles is shown in Figure 3. As can be observed, compared to the curve in bulk aqueous solution, the presence of surfactant micelles can shift the ionization curve to either higher or lower pH values. For example, while the ground-state pKᵣ (and excited-state pKᵣ) of 4-methyl-7-hydroxylavalam cation in water is 4.4 (ca. –1.0), values of 2.25 (0.05), 3.3 (–1.2), and 6.5 (0.3), respectively, were reported in the presence of CTAB, TX-100, and SDS micellar media. Hence organized media can function as pH shift reagents.

Likewise, a shift of the pH value of one unit was reported for tetracaine in the presence of egg yolk PC liposomes and as large as 1–3.5 units for 5-doxylstearic acid and 16-doxylstearic acid in PC liposomes, respectively. Cationic surfactant media typically enhance the acid dissociation (decrease pKᵣ) of organic compounds, whereas anionic surfactant media have the opposite effect (see Figure 3).

The pKᵣ of acids in the presence of CDs is typically larger than (or equal to) that observed in the absence of the CD, whereas the pKᵣ of phenolic compounds is generally smaller than (or equal to) that in the absence of the CD. The pKᵣ’s of seven flavonols were found to increase slightly with increases in the β-CD concentration. Typically, the magnitude of the shifts of the pK values in CDs is not as great as that observed in surfactant vesicle or micellar systems.

The kinetics of the excited-state protolytic dissociation of 1- and 2-naphthols in aqueous solution, micelles, and liposomes has been examined. Many analyte molecules, such as 2-naphthol, when excited in neutral aqueous solution, undergo spontaneous deprotonation as a result of the fact that the pKᵣ of the excited state can be 6–7 units lower than that of the ground state. For

Notes:
- $^a$ The asterisk denotes the singlet excited-state ionization constant.
- $^b$ Refers to 4-(2-pyridylazoresorcinol).
- $^c$ Refers to cetylpyridinium bromide (CPB).
- $^d$ DDAB refers to dodecyltrimethylammonium bromide.
- $^e$ DMPC refers to dimyristoylphosphatidylcholine.
- $^f$ DPB refers to dodecylmethyl propiobetaine.
- $^g$ Refers to the Stern–Volmer constant, $K_{sv}$, for the quenching of dipyrindamole (DIP) by acrylamide in buffer at the indicated pH.$^{(383)}$
- $^h$ Refers to 1-(2-pyridylazo)-2-naphthol (PAN).
- $^i$ Refers to the Stern–Volmer constant, $K_{sv}$, for the quenching of the indicated fluorescent molecule by quencher molecule or ion in aqueous solution or organized assembly system.
- $^j$ Refers to 2-(p-aminophenyl)-3,3-dimethyl-5-cyano-3H-indole.
- $^k$ Refers to 2,6-diphenyl-4-(2,4,6-triphenyl-1-pyridinio)-1-phenolate.
- $^l$ Refers to 9-(3-pyrenyl)monanoic acid.
- $^m$ CMC of etonium surfactant micelles is 2.15 mM.$^{(397)}$
- $^n$ Refers to cationic surfactant 1-ethoxy-carbonylxpentadecyltrimethylammonium bromide.

In the presence of 0.10 M CTAB, these values are 11.6 and 11.5, respectively.$^{(98)}$

As a consequence of such solute $pK$ shifts, the use of an appropriate organized assembly system alters the pH requirements for the fluorescence assay, functioning as pH shift reagents.$^{(404)}$ For instance, in the example, 2-naphthol has a $pK_a$ (in water) of 9.4–9.5, but in the first excited singlet state, the $pK_a^{*}$ drops to 2.8; it is a much stronger acid in its excited state.$^{(403,404)}$ The presence of organized media can impact both those values. In the case of benzimidazole, the $pK_a^{*}$(water) is ca. 13.1, whereas the $pK_a^{*}$(water) is 12.1.$^{(98)}$ However, in the presence of 0.10 M CTAB, these values are 11.6 and 11.5, respectively.$^{(98)}$
determination of ethylenediaminetetraacetate (EDTA), the optimum pH for formation of the fluorescent EDTA–Zr(IV)–Alizarin red X ternary complex is shifted toward a lower range (pH 4.5–5.5) in the presence of CTAB micelles compared to that seen (pH 5.3–6.3) in the absence of micelles. The CTAB micelle medium allows the formation of the complex at more acidic conditions, which leads to an increase in the stability constant of the complex.

Likewise, the optimum pH required for the horseradish peroxidase (HRP)-catalyzed fluorogenic reaction between hydrogen peroxide and p-hydroxyphenylpropionic acid (HPPA) was shifted from 8.0 in aqueous solution to ca. 7.5 in aqueous solution containing CTAB micelles. The lower pH requirement in the presence of CTAB leads to less deactivation of the enzyme, HRP, compared with that observed in bulk aqueous solution.

The effect of micellar and CD organized media upon the position of the keto–enol equilibria of different 1,3-dicarbonyl compounds, as well as on their pK values and reactivity, was the topic of a comprehensive study by Iglesias.

Thus, in some situations, it is possible to utilize organized assembly systems as “pH shift” (or other “equilibrium shift”) reagents to facilitate desired fluorogenic reactions in chemical analysis.

2.3.5 Bulk Solvent and Microscopic Properties of Organized Assemblies

Micellar, vesicular, and CD organized assemblies are fluid, transparent to ultraviolet light, stable, and macroscopically homogeneous. They are particularly attractive for use in analytical spectroscopy in general because they are commercially available, relatively nontoxic, and environmentally benign, and their solutions easy to prepare. Also, because of these characteristics they have been employed in numerous photochemical and photophysical investigations.

In particular, the fluorescence properties of aromatic probe molecules have proved invaluable as a tool to provide information on micellar systems, such as determination of micellar parameters (CMC and N) and estimates of microscopic polarity and viscosity, water content, partitioning between water and micelle phase, permeability for quenchers, etc. A mini review nicely summarizes the influence of the solvent medium on the energy of the electronic states of organic molecules. As a consequence of such medium solvatochromatic effects, fluorescence measurements often exhibit differences between fluorescence parameters [e.g., emission wavelength maximum, $\lambda_{em}$; excited-state lifetime, $\tau$; quantum yield, $\Phi$; FI; etc.] obtained in an aqueous solution relative to that obtained in aqueous organized assembly solutions.

A number of different techniques have been employed to determine the apparent effective microscopic environment experienced by bound solutes in organized systems. Table 1 compares some of the properties of bulk solvents to the microscopic environmental properties experienced by solutes when bound to different organized assembly media. The term micropolarity typically refers to the effective polarity experienced by the solute when bound to a particular organized assembly and is a reflection of the porosity or extent of water penetration into the hydrocarbon portion of that organized medium. A compilation of the effective dielectric constants in organized surfactant media is available. Such results indicate that the apparent dielectric constant of the interfacial region of micelles, bilayers, and microemulsions is substantially lower than that of bulk water (Table 1). In general, the polariy of micellar interfaces decreases with increasing surfactant chain length and surfactant concentration. It decreases with temperature. It is interesting to note that the static dielectric constant of aqueous salt solutions (in the absence of any organized assembly) is considerably lower than with water alone. For example, all salts show a lowering of the dielectric constant; at 21° C, the dielectric constant of aqueous sodium chloride solutions ranges from 73.9 (0.5 N NaCl) to 48.4 (5.0 N NaCl solution). For cationic and anionic surfactant systems, the concentration of ions (counterions) in the micelle Stern layer region has been estimated to be about 3.0 M. For PC vesicles and multibilayer systems, a lower polarity than that of aqueous normal micelles is typically observed. Microemulsion systems exhibit a polarity similar to that of aqueous micelle media. The effective polarity of the CD cavity has been reported to be equivalent to the polarity of an 80:20 (v/v) methanol–water or ethanol mixture. The range of values for the effective polarity of CDs has been thought to be due to the fact that (i) some probe molecules might not be entirely included within the cavity of the CD, (ii) the number of included water molecules present in the complex might be dependent upon the nature of the solute, and (iii) the probes most frequently employed respond primarily to the bulk polarity of the region and their sensitivity to hydrogen-bonding interactions might be very weak. More important, the polarity or microenvironment sensed by a specific probe depends on the position that the probe occupies within the CD cavity.

The term microviscosity or microfluidity is typically a measure of the extent of hindrance experienced by a solubilized molecule for translational motion within a particular micelle, vesicle, or CD organized system. Micellar microviscosity values are sensitive to the reporter molecule’s position in the micelle aggregate. For instance, using the probe dipyrenylpropane as a reporter molecule, the microviscosity of SDS micelles
was estimated to be ca. 19 cP at 20 °C.\(^\text{[89]}\)
However, when diphenylpropane is used as the reporter probe molecule, a considerably smaller value for the microfluidity was obtained, namely \(\eta \approx 4\) cP. Use of \(N, N', N''\)-tetramethyldiaminodiphenylketone hydrochloride as the probe molecule yielded an estimate of 5 cP for the viscosity in SDS.\(^\text{[42b]}\) A value of 4.3 cP has been determined from examination of the excited-state torsional relaxation of the probe 1,1'-dihexyl-3,3,3', 3'-tetramethylindocarboxyanine iodide.\(^\text{[421]}\) Such differences in estimates of microenvironmental parameters can be due to different solubilization sites of the probe molecules, and/or reflect nonisotropic fluidity (or environmental property) in some organized assembly systems. Such influence of the size of the probe molecule upon the observed microfluidity of lipid bilayer/vesicle and bile salt systems has also been reported.\(^\text{[422,423]}\) An excellent discussion of the fluidity parameters of the lipid regions of micelles and liposomes as determined by fluorescence polarization measurements is available.\(^\text{[422]}\)

In most cases, the variation in the \(\varepsilon, \eta, \text{ and } E_{\text{T}(50)}\) values for a particular organized assembly system can be rationalized in terms of the different time-averaged locations for the various probe molecules employed to probe that specific system and in the appropriate choice of the probe and empirical scales employed.\(^\text{[71,80,240,242]}\) It has also been pointed out that in many cases the reported values do not reflect the microenvironment of the micelle-bound probe since they were determined at surfactant concentrations \(<50\) mM\(^\text{[66c]}\) hence there are different degrees of interaction of the probes with their environments.\(^\text{[71]}\) Thus, comparisons between systems should be made only if the same probe molecule was employed using the same technique for determination of the microenvironment parameter under consideration. Also, mixed micelles or organized assembly systems have different binding sites and microenvironments compared to that of their respective individual components.\(^\text{[423]}\) The presence of additives can dramatically impact some of these microscopic parameters as well. For instance, the apparent microviscosity of CTAB was estimated at \(~40\) cP, whereas the values were 200–300 cP or \(~400\) cP for CTAB with added cetyl alcohol or 1-hexadecanesulfonate, respectively.\(^\text{[83]}\)

The reduced fluidity of analytes in surfactant micelles has recently been utilized for analytical advantage. Strong rotational depolarization of fluorescence is typically observed for small molecules in bulk homogeneous solutions. However, when bound to organized assemblies, such small molecules experience a highly viscous, less fluid microenvironment which results in their fluorescence being partially polarized. Yan and Myrick have taken advantage of this and shown that it is possible to differentiate between different xanthene dyes on the basis of their micelle-enhanced steady-state fluorescence polarization (SSFP) even though the dyes’ regular fluorescent emission spectra were almost identical.\(^\text{[424]}\)

Demas et al.\(^\text{[425,426]}\) have described a novel fluorescence technique which allows determination of the solvent environment around solutes, specifically, the degree of solvent (water) accessibility of a micelle-bound solute. Novaki and El Seoud\(^\text{[66c]}\) have reported that the effective water concentrations at the solubilization sites of different solvatochromic probes in cationic micellar media range between 22.1 and 47.8 M, depending upon the specific probe, surfactant micelle, and reference solvent mixture employed. Another report estimated water concentrations of 3.0, 54.0, and 14 M at the solubilization site of 9-anthroate in micelles of Triton X-100, SDS, and DTAC, respectively.\(^\text{[427]}\)

It has been estimated that for ionic surfactant micelle systems the concentration of counterions in the micellar Stern layer is of the order of \(3\) M.\(^\text{[5,418]}\) The refractive index for aqueous micellar solutions has been reported to be in the range 1.3–1.5, depending on the specific surfactant, its concentration, and the presence or absence of other additives.\(^\text{[428–431]}\) Of course, the effects of the refractive index of the solvent system can influence some of the solution-phase photophysical properties of molecules (such as their fluorescence decay times).\(^\text{[430,432]}\)

### 3 ORGANIZED ASSEMBLIES IN ANALYTICAL FLUORESCENCE MEASUREMENTS

A number of specific reviews on the applications of surfactants, \(^\text{[14,433–438]}\) microemulsions,\(^\text{[440,445,446]}\) reversed micelles,\(^\text{[446]}\) CDO\(^\text{[13,173,433–439,447–449]}\), and related media in analytical spectroscopy have been published, each of which typically has a section dealing with fluorescence measurements in such media. Excellent overviews on the utilization of organized assemblies to facilitate luminescence analysis of environmental species have recently been published.\(^\text{[14,173]}\) A review concerning the use of organized assemblies to enhance analytical chemiluminescence measurements is also available\(^\text{[166]}\) (see Chemiluminescence, Electrogenerated).

#### 3.1 Enhancement of Fluorescence Intensity in Organized Media

##### 3.1.1 Effect of Organized Media Upon a Solute’s Fluorescence Properties

Upon transfer from a bulk solvent, such as water, to an organized assembly phase, the luminescence properties (such as excitation and emission wavelengths, \(\lambda_{\text{ex}}\) and...
\( \lambda_{em} \), lifetime, \( \tau \), and emission intensity) of many solutes can be altered, sometimes dramatically.\(^{(14,18,20,40,43,48,439)} \)

For instance, the inclusion of organic compounds in CDs frequently leads to fluorescence enhancements and also a shift of the emission maximum toward shorter wavelengths.\(^{(43,48,45,451)} \)

Figure 4 illustrates the effects of increasing concentrations of different surfactants upon the maximum fluorescence emission wavelength of 4-cyano-4'-propoxybiphenyl.\(^{(180)} \)

With increases in surfactant concentration, the respective micelles of these surfactants form and biphenyl binds to them, resulting in an alteration (shift to shorter wavelength) of the emission wavelength due to a change in the effective microenvironment experienced by biphenyl. The polarity of the respective micelle–biphenyl binding sites is similar to that observed in bulk solvents that are less polar than water, such as DMF or ethanol.\(^{(180)} \)

The different concentration ranges over which the emission wavelength changes merely reflect the fact that these four micelle-forming surfactants have different CMC values (ranging from \( 6.1 \times 10^{-5} \) M for NPh-EO9 to \( 1.2 \times 10^{-4} \) M for NPh-EO30 and \( 8.0 \times 10^{-3} \) M for SDS).\(^{(180)} \)

Numerous other such examples are available.\(^{(452–458)} \)

Upon addition of surfactant micelles, the fluorescence wavelength observed for the Al–lumogallion complex shifts to 552 nm, compared to 584 nm in bulk aqueous solution.\(^{(453)} \)

Likewise, a 15-nm blue shift of the emission wavelength from 350 to 335 nm is observed when PS vesicles are added to aqueous buffered solutions containing cardiotoxin.\(^{(282)} \)

A blue shift of the 8-anilino-1-naphthalenesulfonate (ANS) emission maximum from 515 nm in aqueous solution to 480 nm in DMPC vesicles was reported.\(^{(113)} \)

The fluorescence emission wavelength of 4-aminophthalimide is shifted from 540 nm in water to 513 nm in 2 mM \( \beta \)-CD.\(^{(290)} \)

In the presence of SDS micelles, the emission maxima for 2-anilinonaphthalene-6-sulfonic acid and \( N \)-phenylphthalamine were found to be blue-shifted by 28 and 41 nm, respectively, compared to that in bulk aqueous solution.\(^{(342,343)} \)

The maximum fluorescence emission wavelength observed for the niobium(V)–lumogallion-tartaric acid complex shifted from 630 nm in aqueous solution to 610 nm in the presence of Triton X-100 micellar media.\(^{(454)} \)

For some analytes, red shifts are observed. For instance, the emission wavelength of [2-chloro-3-(2,2-dicyanoethyl)-2-cyclopenten-1-ylidene]methylpyridinium salt shifted from 615 nm in pure water to 626 nm in an aqueous solution of Triton X-100.\(^{(46)} \)

Similar shifts were observed for other carbocyanine-type probe molecules.

More important than the shifts in emission wavelengths are the intensity enhancements observed for many fluorescent species. Many fundamental photophysical studies present data that clearly demonstrate that the fluorescence quantum yields and FI of organic molecules and inorganic metal complexes can be enhanced in the presence of ordered media in comparison to that observed in bulk solvent systems.\(^{(14,20,148,173,282,307,438,448,455–589)} \)

Some representative data is presented in Table 6. It should be cautioned that not all the results noted for a particular compound were obtained under the same standard or optimized conditions, and hence direct quantitative comparisons are not possible in such cases.

However, the bottom line is that addition of surfactant and bide salt micelles, vesicle/lyosomes, and/or CDs can elicit enhanced fluorescence from a range of potential analytes that in many cases can be translated into improved sensitivity in fluorescence assays for those species.

In addition, the fluorescence intensities of a number of other organic molecules were reported to be intensified, but no quantitative data were provided as to the magnitude of such enhancements. Most such reports were in the context of physical, photochemical, or binding studies rather than analytical applications. For example, the luminescence intensity of the following organic compounds was reportedly enhanced by the indicated organized media: doxorubicin (in the presence of \( \beta \)- or \( \gamma \)-CD)\(^{(285)} \); ANS and 2-p-toluidinylnaphthalene-6-sulfonate (by SDS and Triton X-100 micelles or \( \beta \)-CD)\(^{(38,73)} \); perylene (by CTAB)\(^{(60)} \); 2-[\( \beta \)-(dimethylamino)phenyl]-3,3-dimethyl-5-cyano-3H-indole (by \( \beta \)-CD)\(^{(65)} \); pyrene

* Fluorescence enhancement factor refers to the ratio of the FI of the indicated analyte molecule in the presence of the organized medium relative to that observed in a homogeneous bulk solvent under otherwise identical experimental conditions.

b Fluorescence enhancement attributed to protection of the analyte from collisional deactivation due to the presence of the organized assembly.

c Value relative to bulk water; for ionizable analytes, the magnitude of the enhancement value often depends on the concentration of the particular organized assembly system and upon the solution pH.

d Enhancement attributed to increased micropolarity in the lipid bilayer, which diminished competing, nonradiative processes.

e Enhancement attributed to a shift in the position of the solute monomer–dimer–multimer equilibrium; from the multimeric or dimeric form (which is usually weakly or nonfluorescing) in the bulk solvent to its monomeric form (which is fluorescent) in the presence of the indicated organized medium.

f Fluorescence enhancement factors are pH dependent.

g Value relative to that in dioxane as bulk solvent.

h Value relative to that in toluene as bulk solvent.

i Value relative to that in hexane as bulk solvent.

j Values are dependent upon the CD concentration.

k Refers to cetyldimethylhexylammonium bromide.

l Increases in the fluorescence lifetime and emission intensity of the solute observed in the organized system.

m Values relative to that in dioxane as bulk solvent.

n Refers to PS.

o FI is increased in the vesicle system because of the more structured and ordered microenvironment.

p Enhancement attributed to micropolarity effect, e.g. the tryptophan moiety in the toxin, which fluoresces, experiences a less polar environment in the vesicle system, and is also less accessible to quenching from water molecules.

q Auramine refers to N,N,N′,N′-tetramethyldiaminodiphenylketoimine hydrochloride.

r Refers to DMPC vesicles.

s Refers to aminoacyl monomethylamide derivatives of o-aminobenzoic acid, where Xaa = Arg, Phe, Leu, and Glu.

Auramine refers to N, N', N'-tetramethylaminodiphenylketoimine hydrochloride.

x Refers to DMPC vesicles.

y Refers to aminosylic monomethylamide derivatives of o-aminobenzoic acid, where Xaa = Arg, Phe, Leu, and Glu.

z Enhancement attributed to the less polar and more rigid micellar microenvironment which restricts the movement of the analyte molecule.

a Refers to 4′-N,N-dimethylamino-3-hydroxyflavone.
Table 6 (footnote continued)

v Refers to 2-(4-alkylamino-2-hydroxyphenyl)benzothiazole.
w Refers to N,N-dimethyldodecylamine-N-oxide.
x Relative to ethanol or methanol as the reference bulk solvent.
y Enhancement due to binding to micelle which restricts the rotational freedom of the azine molecule.
z Enhancement due to deaggregation of indicated solute molecules in presence of micelle or lipid systems.
aa Enhancement attributed to inhibition of the radiationless decay due to the greater rigidity (greater microviscosity) experienced by the organic compound when bound to the micellar aggregates.
bk Obtained from Naja mossambica.
cm Enhancements attributed to formation of inclusion complexes which results in a decrease in the solutes' rotational freedom and elimination of water molecules in the vicinity of the fluorescent molecules.\(^{(568,583)}\)
dd Refers to 2-(4-aminophenyl)-3,3-dimethyl-5-cyano-3H-indole.
edd Refers to 2-(4-p-toluidinyl)naphthalene-6-sulfonate.
ef Enhancement due to the less polar microenvironment experienced upon binding to the indicated ordered medium.
fg Refers to 4-[2-(2-pyridyl)ethenyl]- and 4-[2-(4-pyridyl)ethenyl]-chalcones.
hh Enhancement attributed to increased medium viscosity accompanying solute binding to the SDS micelles.
iw Refers to 2-chloro-3-(((2,2-dicyanoethyl)-2-cyclopenten-1-ylidene)methyl)pyridinium chloride.
jy Refers to egg PC vesicles.
kx Refers to DMPC.
lh Refers to DPPC.
mn Value depends on the temperature.
oo Refers to dihexadecyldimethylammonium bromide.
op Refers to N,N-bis(2-ethyl-1,3-dioxolane)kryptocyanine.
qq Refers to saturated PC.
rq Refers to the surfactant C\(_2\)H\(_5\)C\(_6\)H\(_2\)SO\(_3\)Na; CMC = 2.0 mM.\(^{(516)}\)
sr Refers to 3,3-dimethyl-2-phenyl-3H-indole.
tt Refers to 2-(p-hydroxy)styryl-3-methylquinolinolizinium bromide.
uu Refers to (dibutylamino)stilbazolium butylsulfonate.
vw Refers to DTAB.
xv Relative to a 1:99 (v/v) acetone–water system.
yw Enhancement attributed to micellar effects upon the nonquinoind lactone–quinoid tautomer equilibrium of the dye molecule, so that a greater portion of the molecules are in the nonaggregated, quinoidal form.
zx Refers to 2-[(p-aminophenyl)-3,3-dimethyl-5-cyano-3H-indole.
zy Relative to methanol as the bulk solvent.
zg Refers to 5,10,15,20-tetra(3-pyridyl)porphyrin.\(^{(499)}\)
hh Refers to 4,4'-[(2-pyridyl)methylene]diphenol diacetate.
bb Relative to 20:80 (v/v) methanol–water solution as bulk solvent system.
cc Refers to 4-(N,N-dimethylamino)benzonitrite.
dd Refers to 4-(N,N-diethylamino)benzonitrite.
ef Enhancement in micellar media reported to be due to the restriction exerted by the micelles on the nonemissive biradical state of tetrachlorodibenzofuran.

ELECTRONIC ABSORPTION AND LUMINESCENCE

(\(\gamma\)-CD)\(^{(283)}\); 1-anilinonaphthalene-8-sulfonate (\(\gamma\)-CD)\(^{(545)}\); carbazole alkaloid derivatives (by \(\beta\)-CD and derivatized \(\beta\)-CDs)\(^{(205)}\); naphthalene (by \(\beta\)-CD and \(\beta\)-CD containing added sodium tetradecyl sulfate, TDSS)\(^{(207)}\); 1-dimethylaminonaphthalene 5-sulfonamide (by CTAB micelles and egg lecithin liposomes)\(^{(75)}\); diphenylpolyenes (DMPC, DPPC, and DODAC vesicles)\(^{(104)}\); anthracene derivatives (by CTAB, CTAC, SDS, Brij-35, and SB-12 micelles\(^{(471)}\); acridine orange (by SDS and other micellar systems)\(^{(70,546,547)}\); fluorescamine-derivatized peptides (by \(\beta\)-CD)\(^{(548)}\); 9,10-dimethylnaphthalene and \(N\)-methylidiphenylamine (by CTAC and CTAB micelles)\(^{(549)}\); coumarin 540A (by \(\alpha\)- and \(\beta\)-CD)\(^{(549)}\); 7-(diethylamino) coumarin laser dyes (by \(\gamma\)-CD)\(^{(550)}\); p-dimethylamino-chalcone (by \(\beta\)-CD)\(^{(103)}\); rhodamine 6F and oxazine 725 dyes (by SDS)\(^{(551)}\); some isomeric estrogens (by \(\beta\)-CD)\(^{(552)}\); eosin (by various nonionic, anionic, and cationic surfactant micelles)\(^{(553)}\); the tripeptide lysyltryptophyllysine (by DMPS)\(^{(134)}\); benzo[a]pyrene (by PC vesicles)\(^{(126)}\); hepatitis A virus peptide (by DPPC liposomes)\(^{(554)}\); DPH (by 1-O-octadecyl-2-O-methyl-DL-glycero-3-phosphorylcholine vesicles and Triton X-100 micelles)\(^{(555)}\); Oxonol VI (by dioleoylphosphatidylcholine vesicles)\(^{(307)}\); 9-aminoacridine and Atabrine (by lipid bilayers)\(^{(306)}\); rhodamine 6Z, rhodamine B, rhodamine 6G, Nile blue, and oxazine 1 (by various surfactant micelle media and PC liposomes)\(^{(102,116,516,556–558)}\); rhodamine B-labeled thyreroxine (by SDS micelles)\(^{(558)}\); Nile red, also referred to as Nile blue A oxazine (by micelles and lipids/liposomes)\(^{(202,559,560)}\); oxonol V (by dioleoylphosphatidylcholine vesicles)\(^{(562)}\); 2-aminoanaphthalene (by CTAB micelles)\(^{(74)}\); dihematoporphyrin ether or ester (by CTAB micelles)\(^{(562)}\); styril derivatives of quinolinizum salts (by CTAB, SDS, and Brij-35 micelles)\(^{(519)}\);
14 quinolinizinium salts (by SDS and Brij-35 micelles)\textsuperscript{(563)}; 11 trans-stibene derivatives (in SDS and CTAC micelles and DPPC and dicetyl phosphate vesicles)\textsuperscript{(242)}; pinacyanol (by SDS micelles)\textsuperscript{(102)}; acrylonan-labeled bovine serum albumin (by SDS, CTAB, and several other cationic micellar media)\textsuperscript{(664)}; amphiphilic ruthenium complex (by C\textsubscript{12}E\textsubscript{6} micelles)\textsuperscript{(565)}; cresyl violet (by SDS micelles)\textsuperscript{(566)}; Triton X-405 (by Brij-35 micelles)\textsuperscript{(567)}; pyronin Y (by SDS and CTAB micelles)\textsuperscript{(357)}; trimethinethiacyanine dye (by cationic vesicles)\textsuperscript{(148)}; phenolphthalein, diphenylamine, phenylfluorone, o-dianisidine, 2,2\textsuperscript{-dipyridylketone azine, phenyl-2-pyridylketone hydrazone, 1,3,5-triphenyl-\Delta\textsubscript{2}\textsuperscript{-}pyrazoline, and 2,3-diphenyl-hexahydro-\Delta\textsubscript{1,7}\textsuperscript{-}isoindazole (by various nonionic surfactant micelles)\textsuperscript{(530)}; naphthylethanol (by \(\beta\text{-CD}\))\textsuperscript{(568)}; N,N-diethylaminoethyl (2,\text{N}-methylamino)benzoate (by egg PC vesicles)\textsuperscript{(515)}; fluorenone (by \(\alpha\text{-CD}\))\textsuperscript{(317)}; 1,4-diphenyl-1,3-butadiene (by \(\gamma\text{-CD}\))\textsuperscript{(569)}; difluval (by \(\beta\text{-CD}\) and \(\gamma\text{-CD}\))\textsuperscript{(568)}; 2,6-dimethylphenol and 2,4,6-trimethylphenol (by \(\beta\text{-CD}\))\textsuperscript{(269)}; triazinylanine derivatives (by DMPC and DPPC vesicles)\textsuperscript{(511)}; aflatoxins (by \(\alpha\text{-}, \beta\text{-, and \(\gamma\text{-CD}\))\textsuperscript{(570)}; cholestatrienol (by a mixed 1-palmitoyl-2-oleoylphosphatidyl-choline–cholesterol vesicle system)\textsuperscript{(571)}; various coumarin derivatives (by \(\beta\text{-CD}\))\textsuperscript{(572,573)}; benzo[a]pyrene (by liposomes)\textsuperscript{(103)}; triazinylanine derivatives (by DMPC and DPPC vesicles)\textsuperscript{(311)}; 3-hydroxy-2-naphthoic acid (by \(\beta\text{-CD}\))\textsuperscript{(574)}; cinalukast and montelukast (by \(\alpha\text{-CD}\) and modified \(\beta\text{-CD}\))\textsuperscript{(14)}; ochratoxin A (by \(\beta\text{-CD}\))\textsuperscript{(522)}; 4-dimethylamino-chalcone (by TX-100 micelles)\textsuperscript{(575)}; and fenoprofen (by \(\beta\text{-CD}\))\textsuperscript{(576)}.

Thus, organized media can produce an increase in FI of a wide variety of organic compounds compared with that obtained in an aqueous (or organic) medium under otherwise identical instrumental conditions. In most instances, such increased fluorescence facilitates analytical determination of those solutes due to enhanced sensitivity, as will be illustrated in a later section\textsuperscript{(99,433,447,500,536)}.

For the following analytes, the presence of organized assemblies has no appreciable effect (or only a very modest enhancement) upon the FI: coumarin-6-sulfonfry chloride (in SDS or CTAB micelles)\textsuperscript{(577)}; coumarin 480 (by CTAB, SDS, and Triton X-100 micelles)\textsuperscript{(578)}; indole (by \(\alpha\text{-CD}\))\textsuperscript{(579)}; uranium-o-hydroxyhydroquinonophthalaein complex (by SDS and Tween 20 micelles)\textsuperscript{(580)}; 1-amino-4-hydroxyanthraquinone, 1,5-dihydroxyanthraquinone, oxine, and 2,2\textsuperscript{-dipyridylketone hydrazone (by various nonionic surfactant micelles)\textsuperscript{(530)}; bimatanes (by \(\beta\text{-CD}\))\textsuperscript{(206)}; fluorenone (by \(\beta\text{-CD}\))\textsuperscript{(207)}; testosterone enanthate, caffeine, ephedrine, chlorthalidone, dihydrochlorothiazide, and spironolactone (by SDS micelles)\textsuperscript{(531)}; 8-methoxysporalen (by \(\beta\text{-CD}\))\textsuperscript{(536)}; and p-cresol (by \(\beta\text{-CD}\))\textsuperscript{(269)}.

The differences in the fluorescence enhancement factor observed (Table 6) for the same solute in different organized assemblies are a consequence of differences in binding interaction between that solute and the specific organized medium and the specific microenvironmental properties experienced by the bound solute. As a result, the fluorescence enhancements depend upon the specific experimental conditions (i.e. type and concentration of the organized assembly, pH, presence of other additives and cosolvents, etc.). Figure 5(a) illustrates the variation of the FI of chlorophyll \(a\) and \(b\) as a function of the concentration of Triton X-100\textsuperscript{(510)}. The intensity increases with Triton X-100 concentration, reflecting the effect
of micelle formation and binding of chlorophyll to the micellar aggregates, after which the intensity levels off. Figure 5(b) illustrates the effect of the concentration of three different charge-type surfactants, nonionic Triton X-100, cationic CTAB, and anionic SDS, upon the FI of (2-chloro-3-(2,2-dicyanoethyl)-2-cyclopenten-1-yldiene)methyl)pyridinium salt. In the case of Triton X-100 and SDS, the FI remains unaffected as the surfactant concentration is increased until the CMC is reached. At and above the CMC, an equilibrium exists between analyte molecules bound to the micellar aggregate and analyte molecules in the bulk solution. As the surfactant concentration is increased further, the number (and sometimes size) of the micelles increases such that the ratio of micellar bound to free analyte molecules becomes progressively larger until saturation is reached. The greater FI in the presence of the neutral surfactant Triton X-100 compared to anionic SDS reflects the fact that the analyte binds to the former much better (probably very small binding to anionic SDS by the anionic carbocyanine solute). In the case of CTAB, the fluorescence decreased with CTAB even below CMC levels (probably owing to quenching by bromide counterions). Once CTAB micelles form, the analyte is incorporated into (and protected by) the micellar aggregate with a resultant increase in its fluorescence emission. The subsequent decrease in fluorescence signal at much greater CTAB concentrations is probably due to changes in the micelle aggregate structure (change in shape from spherical to rodlike), quenching from excess CTAB, and/or quenching from impurities present in the surfactant preparation. Analyte FI versus surfactant concentration profiles similar to those shown in Figure 5(a) and (b) have been reported for many other analyte–organized media combinations.

The fluorescence emission spectra of methyl p-dimethylaminobenzoate as a function of the concentration of β-CD is shown in Figure 6. The emission intensity is observed to increase with increase in the CD concentration because a greater proportion of the analyte molecules present bind to the protective CD cavity upon increasing the CD concentration. In many instances, the limited water solubility of β-CD restricts one’s ability to attain the maximum fluorescence signal from a particular analyte.

As is evident from the data in Table 6, the magnitude of the fluorescence enhancement depends on the organized assembly system employed. For instance, the enhancement factor for the analyte auromine-O ranges from 1.4 in the presence of α-CD to 5.0 in Brij-78 micelles and 7.5 in γ-CD. Nitrobenzoxadiazolyl (NBD)-labeled alkyamines exhibited greater fluorescent quantum yields in the presence of nonionic TX-100 micelles compared to that observed with α-CD or β-CD. Coumarin-6-sulfonyl chloride–derivatized amino acids in a β-CD medium exhibited greater fluorescence emission than in the presence of α-CD. This is presumably due to the fact that the coumarin-6-sulfonyl chloride amino acid derivatives formed stronger inclusion complexes with β-CD relative to α-CD. For the iron(III)–2-pyridinecarbaldehyde-5-nitropyridylhydrazone complex, the enhancement factors are 1.5, 2.1, 2.4, and 4.1 in the presence of micellar cetylpyridinium bromide (CPB), Triton X-100, DTAB, and hexadecyltrimethylammonium bromide, respectively. In addition, even for the same type of organized assembly system, the FI can depend upon the specific chemical nature of the ordered medium.
specific structure and nature of the nonionic surfactant employed.\textsuperscript{105} For metal ion complexes, the metal ion–ligand concentration mole ratio can also have substantial effects on the fluorescence enhancements observed in organized assemblies. Once a given organic or metal chelate analyte is identified for analysis, the most important factor governing the observed fluorescence emission is the nature of the surfactant employed, namely, the charge type and chemical structure of the surfactant, which are the leading properties required for determining the final degree of interaction between the analyte micelles.\textsuperscript{100,101} In general, the better the binding to the organized assembly entity, the greater will be the effect on the solute’s luminescence parameters.\textsuperscript{454} An important factor is the charge of the ordered medium relative to the actual charge of the organic anlyte (or metal chelate).\textsuperscript{100,444} For ionizable species, the pH will obviously also impact on the magnitude of binding observed and, hence, the fluorescence properties.

The degree of fluorescence enhancement is also dependent upon the amount of organic cosolvent present in the organized assembly system.\textsuperscript{106,110,173,271,590} Figure 7 illustrates the effect of added ethanol upon the relative FI of 3,4,4\textsuperscript{-}trichlorobiphenyl (TRCB) in an aqueous nonionic polyoxyethylene(10)lauryl ether surfactant micellar solution.\textsuperscript{107,108} The fluorescence signal in the micellar system remains essentially constant with the percentage of ethanol up to ca. 30%. At this amount of added alcohol, the micellar aggregates disintegrate and the value dramatically drops, increasing slowly again with ethanol concentrations above ca. 40%. This latter increase is practically identical to that obtained in an aqueous ethanol solution in the absence of surfactant.\textsuperscript{108} Other such examples have been reported in the literature. For instance, with 1-naphthol as the fluorophore, a 50% reduction in the fluorescence enhancement factor in the presence of CD was observed if ca. 30% (v/v) methanol, ca. 20% ethanol, or ca. 10% acetonitrile was also present in the solution.\textsuperscript{271,272} Likewise, in the presence of a 0.05 M SDS micellar system, the fluorescence enhancement observed for the diuretic amiloride was 7.4-fold, whereas in the same system with 8% (v/v) added 1-propanol, the factor was only 4.3.\textsuperscript{526}

In the case of CDs, added organic solvents (alcohols or nitriles) can result in either an additional enhancement or diminution of an analyte’s fluorescence emission. If the additive can form a 1 : 1 ternary complex (both analyte and additive included within the CD cavity), then in most instances an additional increase in the FI is observed. For example, addition of 1-butanol further enhanced the fluorescence observed from fluorene in the presence of β-CD by a factor of ca. 1.7.\textsuperscript{903} Likewise, addition of ethanol or acetonitrile enhanced the fluorescence emission of some coumarin dyes in β- and γ-CD.\textsuperscript{327} It was thought that the small organic solvent molecules are also included in the CD cavity along with the coumarin molecule and that such solvent molecules displace water from the cavity which would otherwise quench the coumarin fluorescence.

However, in many situations with other fluorescent species, added cosolvents lead to diminished fluorescence from analyte–CD systems.\textsuperscript{113} This is most often the result of the fact that a rapid decrease in the solute–CD binding constant is observed with increases in the percentage of added organic cosolvents, which can be ascribed to competition between the added cosolvent molecule and the solute molecule for inclusion in the CD cavity. In addition, an increase in the percentage of organic cosolvent means that the bulk solvent system is becoming more hydrophobic and more like the microenvironment of the CD cavity; hence the solute partitions to CD to a lesser extent. The net result of such diminished binding is that less protection is afforded to the analyte molecule and its excited state is more easily deactivated via nonradiative or quenching processes, which results in diminished fluorescence.

The pH can also impact on the magnitude of any fluorescence enhancement of ionizable analytes. For example, in the case of different flavonols, the enhancement factors observed in the presence of β-CD were different under acidic conditions (for the fully protonated form) compared to that under basic conditions (for the fully deprotonated form).\textsuperscript{289,290} In almost all cases, a greater fluorescence enhancement factor was observed for the fully deprotonated flavonol. In the case of 1-naphthol, in the presence of micellar Triton X-100,
SDS, and CTAB, the fluorescence is enhanced by a factor of 90, 66, and 20, respectively, relative to that seen in aqueous solution in the absence of surfactant. Under more basic conditions, the naphthal anion emission is also enhanced in the presence of CTAB and Triton X-100, whereas in SDS its intensity decreases compared with that in water. As noted in an earlier section, the presence of organized media can alter the pH values and function as pH shift reagents.

Of course, the binding of analytes to different organized assemblies does not always result in an enhancement in the luminescence signal. In fact, for some analytes, a diminution in intensity is observed. For example, the fluorescence of the following compounds (or species) reportedly decreased upon binding to the indicated ordered media relative that is observed in the bulk aqueous medium: lumichrome (by β-CD)\(^{204}\), 2-(p-toluidinyl)naphthalene-6-sulfonate (by CTAB)\(^{505}\); 7-ethoxy coumarin and 7-ethoxy-4-methyl coumarin (by SDS and CTAC micelles)\(^{611}\); acridine (by CTAC, DTAC or SDS)\(^{68,593}\); calcein (by bile salt, Triton X-100, and zwitterionic sulfobetaine micelles)\(^{594}\); 4,6,8(14)-triene-3-one steroids (by β- and γ-CD)\(^{595}\); coumarin (by SDS, Triton X-100, and CTAB)\(^{596}\); benzo- and methylquinolinium salts (by CTAB micelles)\(^{593}\); fluorescein (by Triton X-100, Tween 80, and Tween 20 micelles)\(^{402,493}\); PAHs (by CPB micelles, CMC = 0.64–0.73 mM)\(^{597}\); cresyl violet (by Triton X-100 micelles)\(^{596}\); 6-propionyl-2-((dimethylamino)naphthalene, termed Prodan (by SDS and DTAB micelles)\(^{598}\); niobium complex of 8-hydroxyquinoline-5-sulfonic acid (HQS) (by CPB micelles)\(^{93}\); oxandrolone and methyl testosterone (by SDS micelles)\(^{531}\); fluorescein-labeled gentamycin (by SDS micelles)\(^{558}\); and uranium-α-hydroxyhydroquinonophthalein chelate complex (by CTAC)\(^{580}\).

Most of the negative results for CTAB or CPB micelles noted above stem from the fact that the bromide counterion and/or the pyridinium ion quench the luminescence of the indicated analytes. Substitution of other cationic surfactants that do not possess these moieties might result in enhanced luminescence from some of these compounds/complexes. In addition, some organic molecules exhibit weak or no luminescence in organic solvents. Thus, transfer of such compounds from bulk water to an organized assembly phase (which is relatively less polar) results in decreased fluorescence. As an example, the fluorescence of acridine in micellar CTAC, DTAC, and SDS is only 8.0, 10.0, and 29%, respectively, relative to that observed in bulk water. This stems from the fact that acridine fluoresces in water but not in organic solvents. Thus, transfer from the bulk aqueous phase to the less polar microenvironment of the micellar systems results in diminished fluorescence. Obviously, in such situations the use of aqueous-based organized assemblies would not prove advantageous unless one wanted to reduce background luminescence from such species.

### 3.1.2 Mechanism of Fluorescence Enhancements in Organized Assemblies

As illustrated by the data in Table 6, a variety of organic molecules (and also metal complexes) exhibit enhanced fluorescence upon binding to surfactant micellar or vesicle/liposome aggregates or CD molecules. Upon such incorporation, a number of potential mechanisms/factors are thought to be responsible for intensified luminescence, all of which are due to increases in the rate of the radiative process relative to the various competing nonradiative processes. These factors include shielding of the analyte species from quenching by bulk water, increased local viscosity in the binding site with concomitant reduction by oxygen quenching, reduced accessibility to solvent-borne quenchers and, perhaps, reduced quenching (rates) due to the more rigid local microenvironment of the particular organized assembly. As a consequence, the fluorescence quantum yield (and singlet excited-state lifetime) of the analyte fluorophore is often greater when it is “bound” to an organized assembly system relative to that observed in aqueous solution.\(^{95,454,590,599–602}\)

In particular, isolation of analyte molecules which contain hydrogen-bonding moieties from water or other protic solvents possessing O–H or N–H bonds eliminates quenching from those solvent molecules and gives rise to enhanced fluorescence quantum yields (and intensity). Thus, binding of such analytes possessing amino or hydroxyl moieties to organized assemblies would be expected to offer the prospects of enhanced fluorescence. In addition, it was reported that enhanced fluorescence in the presence of surfactant micelles is expected for organic analytes with nonrigid structures and/or that possess several phenyl groups in close proximity. For acyclic azine molecules, transfer from a bulk solvent to a host micelle is thought to limit the rotational freedom of the azine molecule, leading to greater fluorescence efficiency. In some instances, particularly in the case of metal chelate complexes, a portion of the intensified fluorescence can result from an increase in the molar absorptivity of that complex in the organized medium relative to that in a bulk solvent. In the case of some metal complex species, enhanced intermolecular (or intramolecular) energy transfer efficiency also contributes to the intensified fluorescence observed in such systems.\(^{1275,590,604}\)

Additionally, the presence of organized species eliminates (or minimizes) alternative structures (dimers, aggregates, acid–base forms, etc., which have different
fluorescent and dynamic properties) for the analyte.\(^{(35)}\) For some analytes, particularly dyes and some drug molecules, the addition of organized media causes increases in fluorescence as a consequence of their ability to alter the degree of aggregation of the analyte molecules.\(^{1100,501,516,555,556,605–613}\) Typically, the aggregated (dimer, tetramer, and multimer) forms of organic species exhibit weak or no fluorescence; hence deaggregation of the multimeric form due to the presence of the organized media and binding of the monomeric form (which exhibits greater fluorescence efficiency) leads to intensified luminescence.

For instance, the dimerization constants for the dyes MB, acridine orange, MO, and rhodamine R6G in water were reported as ca. 2300, 5200, 9200, and 5600 M\(^{-1}\), respectively.\(^{(606,614)}\) ‘‘Dipole–dipole interactions within the resonating dimeric structure and/or a twisted molecular structure in the dimeric molecule can result in significant fluorescence quenching.’’\(^{(547)}\) The presence of appropriate organized media (i.e. surfactant present well above the CMC) can shift the monomer \(\rightarrow\) dimer equilibrium to the left with resultant enhanced fluorescence from the monomeric form of the dye.\(^{(547)}\) The addition of Triton X-100 to an aqueous solution of rhodamine 6G prevents such dye aggregation, which permitted development of the first continuous-wave laser.\(^{(607)}\) The addition of CD to relatively concentrated rhodamine-containing aqueous solutions also resulted in enhanced fluorescence (due to a shift in the dimer \(\rightarrow\) monomer equilibrium).\(^{(605)}\) However, if CDs were added to less concentrated rhodamine solutions, then the fluorescence due to the rhodamine was somewhat quenched.

CDs were also utilized to control the aggregation equilibria and state of the dyes oxazine 1 perchlorate and oxazine 170 perchlorate.\(^{(610)}\) Also, in water, cyanine dyes slowly form dimers and H aggregates such that the fluorescence of the monomer decreases. However, in the presence of SDS micelles, no dye aggregation occurs and only monomer fluorescence is observed.\(^{(350)}\) Likewise, Triton X-100 or CTAB micelles solubilize chlorophyll in its monomer form, whereas in water, chlorophyll aggregates to different extents.\(^{(615)}\)

### 3.2 Utilization of Organized Assemblies to Improve Fluorescence Methods for Inorganic and Organic Analytes

In general, new limits of sensitivity, and often improved selectivity, can be achieved in fluorimetric methods by analytically exploiting the unique properties offered by organized assembly systems. The use of micellar, vesicle, and CD media to enhance the FI of analyte molecules (species) has led to the development of fluorimetric methods that exhibit improved sensitivity,\(^{(96,99} – 106,113,205 – 207,229,307,395,405,454,465,470,500,532,581,599,616–627\) and also aids in the solubilization of the organic analyte or metal chelate,\(^{(107,196,518,599,628,629)}\) eliminating the need to use organic solvents.\(^{(187,449,630,631)}\) Other advantages reported include better selectivity,\(^{(307,405,532,599,616} – 622,629\) wider calibration range (linear dynamic range),\(^{(589,599)}\) greater accuracy and reproducibility,\(^{(599)}\) greater flexibility in the choice of optimum pH,\(^{(619,629)}\) and method convenience.\(^{(518,599)}\) Greater stability of the luminescent species,\(^{(581,590)}\) and, in some cases, eliminating the need for a prior extraction, cleanup, and/or chromatographic separation step.\(^{(518,583,624,633,634)}\) Specific examples of the utilization of organized assemblies to improve the analytical performance of fluorimetric methods for a variety of organic and inorganic analytes are outlined in the following sections.

#### 3.2.1 Determination of Organic Analytes

Various types of organized assembly systems have been employed to enhance or improve fluorimetric methods for the determination of organic compounds.\(^{(14,173,635–677)}\) Table 7 summarizes the conditions, analytical parameters and benefits derived from use of different organized media for the improvement of fluorimetric assays for some selected organic analytes. In most instances, the primary benefit of the organized medium is enhanced sensitivity. For instance, analytical fluorescence calibration data were determined for 13 PAHs in the presence of Brij-35 micelles.\(^{(222)}\) Detection limits ranged from 0.005 ng mL\(^{-1}\) for chrysene to 0.2 ng mL\(^{-1}\) for naphthalene. The sensitivity and selectivity of PAH determinations in this medium are better than those obtained in methanol. The Brij-35 modified fluorescence method was evaluated for the determination of pyrene, benzo[a]pyrene, and benzo[g,h,i]perylene in particulate air samples.\(^{(222)}\) A method for the resolution of multicomponent PAHs in micellar media via use of linear variable angle fluorescence and chemometric techniques has been reported.\(^{(481)}\)

Derivative synchronous fluorescence spectrometry using polyoxyethylene(10)lauryl ether (C\(_{12}\)E\(_{10}\)) micelles was employed to determine simultaneously 3,3′, 4, 4′-tetrachlorobiphenyl (TTCB) and 2,3,7,8-tetrachlorodibenzo-furan (TTCDF), with detection limits of 5.3 and 1.3–2.7 ng mL\(^{-1}\), respectively.\(^{(630)}\) The presence of C\(_{12}\)E\(_{10}\) enhanced the FI of TTCB and TTCDF by factors of ca. 11 and 40, respectively, compared to that observed in an aqueous 2% (v/v) ethanol solution. Likewise, a simultaneous synchronous fluorimetric method for determination of benzo[a]pyrene and perylene in Triton X-100 micelles was developed, with detection limits of 0.27 and 0.30 ng mL\(^{-1}\), respectively.\(^{(640)}\) Binary mixtures of dibenzo[a,c]anthracene and coronene were determined...

in CTAB micelles by synchronous fluorescence spectrometry, with detection limits of 0.20 and 0.22 ng mL\(^{-1}\), respectively.\(^{474}\) The simultaneous determination of chrysene, perylene, and coronene was also reported, with detection limits of ca. 0.14 ng mL\(^{-1}\) for each of these PAHs. Constant-energy synchronous luminescence spectrometry (CESLS) in conjunction with SDS micelles allowed for the simultaneous identification and determination of benz[a]pyrene, perylene, and pyrene in a mixture.\(^{641}\) The presence of the micelles obviated the need to use an organic solvent and greatly enhanced the fluorescence signals, allowing detection of these PAHs in the low nanogram per milliliter levels (limits of detection ranged from 0.34 to 0.70 ng mL\(^{-1}\)).\(^{641}\)

The utilization of micellar benzylidimethylhexadecylammonium chloride allowed for the determination of indole-4-carboxylic acid with a detection limit of 1.0 ng mL\(^{-1}\).\(^{307}\) CDs were employed to enhance the fluorescence of the pesticides bendiocarb and promecarb and detection limits of 0.57 and 0.091 μg mL\(^{-1}\), respectively, were achieved.\(^{539}\) The fat-soluble vitamins; A and E, can be easily solubilized in aqueous micellar solutions,
which allowed their fluorimetric quantification in milk samples\(^\text{106}\) with detection limits of 54.0 and 55.2 ng L\(^{-1}\), respectively, reported with Brij-35 as the micelle.

HRP-catalyzed fluorogenic reactions involving hydrogen peroxide with substrates such as HPPA has frequently been utilized in clinical and biochemical assays. In the conduct of such assays, a sequential approach or compromise of conditions is required since the enzyme activity, reaction rate, and product FI are not at maximum at the same pH values.\(^\text{630}\) However, if the reaction is conducted in the presence of cationic surfactants, such as CTAB or CTAC, this difficulty can be overcome, as the reaction rate is 2.4–2.6 times greater than that in an aqueous solution. A CTAB micellar modified FIA method for the determination of HRP was developed with a linear dynamic range of 0.029–290 mg L\(^{-1}\) HRP (\(\lambda_{\text{ca}} = 300\) nm, \(\lambda_{\text{sem}} = 405\) nm).\(^\text{630}\) The micellar rate and pH effects on this reaction sequence should also be applicable for the enhancement of the fluorimetric determination of hydrogen peroxide.

The FI of an adduct of arginine with 2,3-naphthalene-dicarboxaldehyde (\(\lambda_{\text{ca}} = 462\) nm, \(\lambda_{\text{sem}} = 520\) nm) in a weakly alkaline solution was enhanced ca. 12-fold by the addition of \(\beta\)-CD.\(^\text{642}\) The reaction is highly specific for arginine, so no prior separation step is required in the procedure.

HRP catalyzes the reaction of acetaminophen and hydrogen peroxide with the formation of several unknown fluorescent products. The addition of Triton X-100 results in a fivefold increase in the observed fluorescence from this system.\(^\text{643}\) This system is thought to be amenable to coupling to other reaction systems for the determination of substrates (or enzymatic activity). As an example, a linear calibration curve was obtained for the determination of substrates (or enzymatic activity). To be amenable to coupling to other reaction systems for the use of SDS micelles in the chromatographic mobile phase with fluorescence detection.\(^\text{682}\)

Several articles review the enhanced fluorescence effects observed for dansylated amino acids due to the micellar mobile phases utilized for their HPLC separation,\(^\text{14,463}\) as well as enhancements in the detection of environmental species separated by HPLC (or CE) that utilized micelles (or CDs) in the mobile phase (or run buffer).\(^\text{14,449}\) A reversed phase HPLC method utilizing CDs in the mobile phase to enhance fluorescence detection was employed to determine aflatoxins in food and agricultural products.\(^\text{649}\) Capillary electrophoresis utilizing a mixed \(\beta\)-CD/sodium deoxycholate run buffer system was found to resolve the optical isomers of D/L-serine (as their naphthalene-2,3-dicarboxaldehyde (NDA) derivatives) with laser-induced fluorescence as a means of detection (limit of detection was 3.0 \(\times 10^{-5}\) M).\(^\text{650}\) Alanine, glutamate, and \(\gamma\)-aminobutyric acid were also determined using fluorescence detection following their CE separation with a mixed micellar (SDS and sodium cholate) run buffer (detection limits in the range of 11–40 nM).\(^\text{647}\) In addition, catecholamines and amino acids (derivatized with 4-chloro-7-nitro-2,1,3-benzoxadiazole, NBD) were separated and determined by CE via use of SDS micelles in the run buffer. The SDS served to improve the fluorescence of the NBD-labeled catecholamines.\(^\text{456}\) The CE analysis of the mycotoxin zearalenone with CD enhanced fluorescence (limit of quantitation = 5 ng g\(^{-1}\) for maize sample) has been reported.\(^\text{538}\)

The effect of SDS on the fluorescence observed from histone–ANS complexes has been reported.\(^\text{651}\) The enhancement of ANS fluorescence caused by different groups of histones in the presence of SDS is roughly the same. This allowed the development of an ANS staining method for histones that is rapid, economical and simpler than the existing method for such staining of histones separated via sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE).

Enhanced fluorescence due to the presence of organized assemblies can also sometimes be employed to determine the concentration of that organized component. For example, a very sensitive fluorescence assay for phospholipid vesicles using DPH has been reported.\(^\text{486,555}\) The FI of DPH is proportional to the phospholipid concentration, with a detection limit of
0.70 nmol reported.\(^{(480)}\) This optimized method compared favorably with the classical, conventional methods for analysis of such vesicle systems in terms of sensitivity, accuracy, and convenience.

An HPLC method in which the fluorescence enhancement of probe molecules was utilized as the detection mode has been reported for the determination of CDs.\(^{(271, 652, 653)}\) Addition of the fluorescent probe molecule to the mobile phase results in an \textit{in situ} complexation (with resultant enhanced FI), making use of the postcolumn reaction detection system unnecessary. With 1-naphthol as the probe molecule in the mobile phase, a detection limit of 90 pmol was reported for \(\beta\)-CD.\(^{(271)}\) Use of 2-\(p\)-toluidinonaphthalene-6-sulfonate (TNS) as the probe molecule resulted in HPLC mass detection limits of 3.7, 0.050, and 0.14 \(\mu\)g for \(\alpha\)-, \(\beta\)-, and \(\gamma\)-CD, respectively.\(^{(653)}\) Derivatives of \(\beta\)-CD can be detected in an analogous manner. In similar fashion, TNS or ANS was utilized in the run buffer to enhance the fluorescence detection of nonabsorbing analytes (anionic surfactants such as SDS) in CZE and micellar enhanced/electrokinetic capillary chromatography (MECC or MEKC).\(^{(471, 495)}\) Detection limits of 0.1–0.4 mM SDS were reported, although the reproducibility was relatively poor. Also, any analyte that partitions into the micelle (present as part of the run buffer) will displace some of the added fluorescent probe molecule with a concomitant decrease in the fluorescence signal, which allows indirect detection of nonabsorbing solutes in MECC.\(^{(495)}\)

For instance, using ANS as the probe in conjunction with SDS in the run buffer allowed indirect fluorescence detection of the analytes phenol, 3,5-dimethylphenol, and naphthalene. In addition, a flow-injection titration method has recently been reported for determination of surfactants (SDS, SB-12 (\(N\)-dodecyl-\(N, N\)-dimethyl-3-ammonio-1-propanesulfonate), Triton X-100, CTAB) based upon the enhanced fluorescence observed for TNS in their presence.\(^{(653)}\)

There are some reports concerning the use of dipping or spray reagents containing organized surfactant assemblies to enhance fluorescence detection of organic analytes following their separation by thin-layer chromatography (TLC). For example, the use of Triton X-100 dissolved in chloroform or benzene as a spray reagent enhanced the fluorescence signal of the analyte ethoxyquin by a factor of \(>200\).\(^{(654)}\) After application, the organic solvent was evaporated, leaving the pure, viscous Triton X-100 on the silica gel TLC sheet, which resulted in the enhanced emission signal. Likewise, detection of 7-fluoro-2,1,3-benzoxadiazole-4-sulfonate (SBD) derivatized glutathione was improved by a factor of ca. 2.0 via the use of organized assemblies in a fluorescent enhancer dipping reagent following separation via high-performance TLC on silica gel.\(^{(655)}\)

For this analyte, the fluorescence enhancement ratios obtained were 1.80, 1.85, 1.86, and 2.16 for 40\% (v/v) Triton X-100 in toluene and 20 mM aqueous solutions of \(\alpha\)-, \(\gamma\)-, and \(\beta\)-CD, respectively.\(^{(655)}\) The detection limit achieved was 17 pg of glutathione per spot.\(^{(656)}\) A fiber-optic remote sensor for \textit{in situ} fluorometric quantification in TLC has also been reported.\(^{(657)}\) The fluorescence signal was again enhanced by dripping the silica gel plates in a mixture of Triton X-100 and chloroform. Detection limits of 5.3 and 6.4 \(\mu\)M were reported for the analytes acepromazine and propiomazine, respectively.\(^{(657)}\) Significant enhancements in fluorescence for dansylated amino acids and aromatic hydrocarbons were observed on silica gel and alumina TLC plates when using CTAC or NaC micellar or \(\beta\)-CD spray reagents.\(^{(658)}\)

Some of the same surfactant micelle systems (nonionic, zwitterionic) that can be employed to enhance the FI from organic analytes can also be utilized above their cloud point (CP) for extractive preconcentration (see \textit{Waste Extraction Procedures: Cyanogen Chloride and Cyanogen Bromide Analysis in Drinking Water}). Although nonionic surfactants dissolve in aqueous solution to form micellar aggregates, above a temperature referred to as that surfactant’s CP, which is characteristic of the surfactant employed and the conditions, the surfactant phase separates from the bulk aqueous phase akin to a conventional liquid–liquid extraction process\(^{(94)}\) (for a review, see Hinze et al.\(^{(659)}\)). Thus, via the use of appropriate surfactants and conditions, it is possible to combine this CP extraction with fluorescence detection to achieve high concentration factors (from the CP extraction step) and also fluorescence enhancements due to the presence of the surfactant-rich aggregate phase, both of which serve to improve analyte detectability. As examples of this technology, the nonionic surfactant Genapol X 80 was employed in the CP extraction and fluorescence detection of the pesticides napropamide and thiabendazole from water and soil samples.\(^{(660)}\) The fluorescence enhancement factors obtained in the surfactant-rich phase were 1.2–2.0 for these two pesticides. Detection limits below 0.2 \(\mu\)g L\(^{-1}\) were achieved with recovery rates of up to 95\%. In addition, the acid-induced CP extraction using SDS served as a preconcentration step prior to the fluorimetric determination of a number of PAHs.\(^{(661)}\)

The presence of micellar media can often enhance the photostability of organic molecules. For instance, while irradiation of a cyanine dye in aqueous solution with a 450 W Xe lamp through a 400 nm cut-off filter resulted in a complete depletion of the dye within 30 min, no fading whatsoever was detected after 24-h irradiation in the presence of an SDS micellar solution.\(^{(39)}\) Likewise, rhodamine 6G was found to be much more stable in SDS micellar media than in bulk methanol or ethanol.
when submitted to near-ultraviolet/visible (UV/VIS) illumination from a continuous xenon arc lamp. This is a consequence of the fact that the photodegradation reaction(s) is inhibited in the presence of micellar media. Pyridoxal is oxidized in the presence of cyanide ion to form 4-pyridoxalactone as the fluorescent product. The use of cationic CTAB resulted in an enhancement of both the reaction kinetics (by a factor of ca. 2) and also the quantum yield of the product. The limit of detection of pyridoxal using the micellar-enhanced fluorescent FIA approach was 0.17 ng, which is three times lower than that achieved in an aqueous solution in the absence of surfactant.

Micellar media have also been employed to enhance some fluorescence immunoassay techniques for determination of biological/clinical molecules. Fluorescent dyes are typically employed to label analyte molecules in ligand binding assays. The assay requires that there be a fairly large difference in the fluorescence properties of the bound compared with the free labeled analyte. Halfman et al. reported that SDS micelles quenched the emission of free fluorescein-labeled gentamycin without impacting the emission intensity of labeled gentamycin bound to gentamycin antibody, thus fulfilling the requirement for a large fluorescence difference between the bound and free labeled species. The micellar quenching effect thus allowed the development of a convenient homogeneous fluorescence immunoassay for gentamycin based only on FI measurements. Guidelines for the design of similar assays for other analytes and the charge-type surfactant micelles that would be required were also discussed. More recently, specially derivatized CDs have been developed that allow for the quenchfluorimetric determination of organic species, including enantiomeric compositions. For instance, a β-CD modified to contain the dansyl fluorophore was synthesized and shown to serve as an enantioselective fluorescent sensor for amino acids. In the absence of enantiomeric analytes, the dansyl group, although chemically bound to the CD, is included in the CD cavity and exhibits intense fluorescence. In the presence of an analyte, the analyte can displace the dansyl group, which when in contact with bulk solvent exhibits much diminished fluorescence. The decrease in dansyl fluorescence is proportional to the analyte concentration. Such approach has been employed as a means of sensing amino acids as well as endocrine-disrupting chemicals. Other fluorescent moieties have been appended to cyclodextrins for application as sensors (see Fluorescence-based Biosensors; Biosensor Design and Fabrication) for other analyte groups.

The quenching of fluorescence from acridine orange sensitized rhodamine 6G (or B) system in sodium dedecylbenzenesulfonate micelles upon the addition of analytes (such as erythromycin and vitamin B12) has been employed to quantitate those analytes. In closing this section, it should be noted that more information and examples concerning the use of CDs in analytical fluorimetry and diagnostics can be found in a book chapter and a recent review article. In addition, a review by McGown et al. focuses on luminescence measurements in bile salt surfactant systems.

### 3.2.2 Photochemically Induced Fluorescence (PIF) Detection

For weakly fluorescent and nonfluorescent analytes, derivatization to convert the analyte into a more detectable product (i.e. better fluorescing) constitutes a means of enhancing that analyte’s detectability. In addition to chemical reactions, an alternative approach is to use a photochemical reaction. In this case, intense UV/vis radiation converts nonfluorescent or weakly fluorescent analytes of interest into highly fluorescent products. Such a PIF approach has been employed as a postcolumn derivatization technique for detection in chromatographic systems.

A flow-injection fluorimetric method for determination of vitamin K$_1$ based on a photochemical reaction in the presence of Triton X-100 micelles has been reported. As previously noted, the primary function of the micellar media was to enhance the stability and solubility of different reactive species formed during the photochemical reaction. This method permits the determination of vitamin K$_1$ in the 10$^{-6}$–10$^{-4}$ M concentration range. The anionic surfactant SDS was employed in the HPCL-PIF determination of K vitamins. A FIA-PIF method for the determination of menadione in the presence of SDS with a detection limit of 0.18 mg mL$^{-1}$ has been developed by Perez-Ruiz. The determination of phylloquinone in fruits and vegetables by FIA with SDS micelle–enhanced PIF (detection limit 0.05 µg mL$^{-1}$) has been reported.

A rapid micellar-enhanced PIF-FIA method for the determination of nonfluorescent sulfonylurea herbicides in water has been developed. In this application, the primary purpose of incorporation of surfactant micellar SDS or CTAC in the carrier stream was to improve the solubility of the herbicides in an aqueous medium. In addition, the photosinduced fluorescence signals were greater by a factor of 1.1–4.1 for the four herbicides examined in the presence of the micelles compared with those in aqueous solution in the absence of surfactant micelles. Detection limits of 0.2–0.5, 0.1–0.2, 0.2–0.8, and 1.0–6.0 ng mL$^{-1}$ were reported for the herbicides chlorosulfuron, methsulfuron-Me, 3-rimsulfuron, and sulfometuron-Me, respectively. In similar fashion, a photochemical–spectrofluorimetric method
for determination of two pyrethroid insecticides and four phenylurea herbicides using an anionic and/or cationic surfactant micellar medium and CDs has been reported.\(^{672,674}\) Likewise, such micellar-enhanced photochemically induced fluorescence approaches have been employed for the determination of other herbicides (e.g., mecoprop, chlorphenoxyacid, phenylurea residues, etc.) using time-resolved and/or flow-injection PIF techniques\(^{449,567,675,676}\) (see Phenyl- and Sulfonylurea Herbicides: Single Class, Multiresidue Analysis of).

Upon irradiation, mazindol, an anorectic agent, forms a photoproduct whose fluorescence is much greater than that of mazindol itself. Irradiation of mazindol solutions in the presence of micellar SDS provokes a further enhancement in their fluorescence and the maximum FI is reached faster than in the absence of the surfactant.\(^{529}\) After a 5-min irradiation time, the FI is roughly 42 times greater than that observed in aqueous solutions. This micellar-enhanced photochemical method for mazindol has a detection limit of 3.6 ng mL\(^{-1}\) (in the absence of SDS the detection limit is 65 ng mL\(^{-1}\)).\(^{529}\)

The effects of different CD media upon the photolysis of dissolved anthracene by fluorometry has been reported. Derivatized CDs promoted the photolysis reaction to a greater extent relative to the native, underivatized CDs.\(^{191}\) In view of the effect of organized assemblies upon the rate of photophysical processes, it is thought that this general type of application deserves much greater attention and will lead to the development of very sensitive assays for nonfluorescent or weakly fluorescent analytes. In particular, the use of this general PIF approach as a means of HPLC detection\(^{677}\) in conjunction with micellar or CD mobile phases (or run buffers) in liquid chromatography (or capillary electrophoresis or electrochromatography) should prove to be very fruitful.

### 3.2.3 Fluorimetric Determination of Inorganic Ions and Organometallic Species in Organized Media

The use of surfactant micellar systems and, to a much lesser extent, CDs can increase the stability and solubility of many organic ligands and metal complexes in water and, when such metal complexes are fluorescent, a marked enhancement in the fluorescence signal is frequently observed. Consequently, the use of such organized assemblies can improve many existing spectrofluorimetric methods by increasing their sensitivity and/or eliminating the need for extraction procedures or the use of mixed aqueous–organic solvents.\(^{149,377,588}\) In addition, as has been previously noted, the possibility of conducting reactions and forming metal chelates in micellar (or other organized) media that are not observed in a bulk homogeneous solvent system can lead to new improved fluorescence methods for select inorganic species.\(^{678–721}\) Some representative data in this regard is summarized in Table 8.

The fluorescence of different metal ion–morin complexes has been enhanced by the presence of surfactant micelles.\(^{681,680–684}\) For example, cationic surfactants such as CTAB enhanced the intensity of Nb(V) and Ta(V) complexes, that of the former by ca. 80–400-fold.\(^{100,628}\) The quantum yields of the morin–Nb(V) complex (pH 3.0) were reported as ca. 0, 0.292, 0.30, and 0.32 in water, ethanol, aqueous cetylpyridinium chloride (CPC) (hexadecylpyridinium chloride) micelles, and aqueous CTAB micelles, respectively.\(^{381}\) The molar absorptivity values for the morin–Nb (V) complex at the excitation wavelength in the micellar media were greater relative to that seen in water or ethanol as bulk solvents.\(^{381}\) Nonionic surfactants, such as Genapol PR-20, enhanced the intensity of the Al(III), Pb(II), and Zn(IV) complexes of morin by factors of 8.0, 9.0, and 75, respectively.\(^{622}\) Triton X-100 micellar media enhanced the fluorescence observed from the morin–Ta(V) and morin–Nb(V) complexes by factors of 85 and 49, respectively.\(^{100}\) The FI of the morin complexes of Zr(IV), Hf(IV), Al(III), Ga(III), In(III), and Sb(V) were enhanced by factors of ca. 2–13 in the presence of anionic SDS micellar media.\(^{681,685}\)

In addition to enhanced sensitivity, the presence of organized assemblies in certain instances can serve to reduce the number of potential interferences. For example, in the fluorescence determination of Al(III) via the use of the complexing agent morin, in nonionic surfactant micelles, interference due to Cr\(^{3+}\), Mg\(^{2+}\), NH\(_4\)\(^+\), and PO\(_4\)\(^{3–}\) was eliminated.\(^{622}\) In fact, in the absence of morin, phosphate ion seriously interferes with this method. However, this interference is completely eliminated owing to the presence of the micellar medium.

Dasgupta et al. conducted a comprehensive study of the fluorescence properties of the metal complexes of HQS in aqueous, mixed aqueous (water–DMF), and aqueous surfactant CTAC media.\(^{686,687}\) Modest to significant increases in fluorescence intensities (enhancements in the range 1.2–10.2-fold) were observed in the presence of the surfactant CTAC medium for the metals Mg(II), Ca(II), Sr(II), Ba(II), Al(III), Cd(II), and Zn(II). The optimum pH for complex formation (and FI) was shifted (reduced) by 1–2 units in the CTAC system.\(^{686}\) In addition, the pH range for maximum fluorescence was extended in this system. It was also noted that the presence of iron(III) quenches the fluorescence of these metal–HQS complexes and that the presence of the CTAC medium accentuates this quenching effect. The simultaneous determination of Al\(^{3+}\) and Zn\(^{2+}\) by first- and second-derivative synchronous fluorimetry via the use of HQS in the presence of CTAB has also been reported.\(^{688}\)

$\Delta \lambda = 110$ nm, LDR = 32–4000 ng mL$^{-1}$, $D_L = 3.0$ ng mL$^{-1}$ | CTAB enhanced FI by factor of ca. 31.0 and lowered the $pK_a$ of morin | 675        |

(continued overleaf)
Fluorimetric methods for Al$^{3+}$, Mg$^{2+}$, and Zn$^{2+}$ based upon the formation of their 8-hydroxy-7-idoquinolinol-5-sulfonic acid chelates in the presence of cationic surfactants such as CTAB have also been reported by other groups.\(^689\)–\(^694\) CTAB micelles enhanced the fluorescence observed for some of these systems, allowing better detection limits. For instance, the sensitivity of the fluorimetric procedure for Al(III) improved by a factor of 8.0 in the presence of CTAB.\(^690\)

The use of SDS micelles in the mobile phase allowed the reversed-phase HPLC separation and fluorescence detection of Al(III) as its 8-quinolinolato complex.\(^695\) The FI was about four times greater than in bulk homogeneous solution, allowing a limit of detection of 1.0 ppb. In another report, micellar liquid chromatography with a CTAB micellar mobile phase allowed for the determination of 10 $\mu$g mL$^{-1}$ Al(III) as its HQS complex.\(^696\) The effect of CPB, CTAB, and Triton X-100 micellar media upon the Ta(V), Ti(V), Al(III), and Nb(V) chelates with lumogallion, ferron, quercetin (3,3',4',5,7-pentahydroxyflavone), morin (3,5,7,2',4'-pentahydroxyflavone), oxine-5-sulfonic acid (HQS), and Alizarin red S has been reported.\(^101\),\(^678\)\(^696\),\(^697\)

In most instances, the presence of these surfactant micelles dramatically enhanced the FI. Mechanistic aspects of these systems and factors impacting on the fluorescence enhancements were discussed.\(^101\),\(^678\) The fluorescence characteristics of the gallium(III) chelate formed with lumogallion, hexyl-lumogallion, and dodecyl-lumogallion in the presence of surfactant micellar systems have been reported.\(^698\),\(^699\) A 10-fold increase in the quantum efficiency of the Ga(III)–hexyl-lumogallion chelate was observed in the presence of the nonionic surfactant polyethylene glycol monolauryl ether.\(^698\) Gallium was easily determined in the parts per billion (ppb) range using this micellar-modified fluorimetric procedure.

A Brij-35-enhanced FIA/fluorimetric method for the determination of aluminum(III) based on the formation of the Al−lumogallion complex has been developed.\(^453\) The detection limit was 0.15 nM, making it one of the most sensitive assays for Al(III). The method is very sensitive, easy to use, and rapid (cycle time 3.0 min).

Triton X-100 micellar medium was utilized as the extraction medium (CP extraction procedure) to extract the Al(III)−lumogallion complex from water (extraction efficiency 72%).\(^700\) The surfactant-rich medium also resulted in a 2.3-fold increase in the FI compared with that observed in bulk aqueous solution. The detection limit attained was 0.05 ppb Al(III).

The sensitivity of the spectrofluorimetric method for Ga(III) with 1-(2-pyridylazo)-2-naphthol (PAN) in the presence of SDS micelles is ca. 20 times better than
that obtained in a 20:80 (v/v) ethanol–water solvent system.\(^{106}\)

The fluorescence reactions of Ti(IV) and Ta(V) ions with pyrogallol red, bromopyrogallol red, Alizarin red S, morin, and 8-quinoilinol derivatives have been evaluated as the basis for the fluorimetric determination of these metal ions in the presence of surfactant micellar media.\(^{701}\)

The effects of β-CD and hexadecylpyridinium bromide, CTAB, and SDS surfactant micellar media upon the fluorimetric properties of the metal chelate complexes formed between 2-(2-hydroxyphenyl)benzoxazole and Al(III), Be(II), Ga(III), and Zn(II) have been reported.\(^{702}\)

The use of flavones (flavonol, chrysin, fisetin, quercetin, morin, etc.) as fluorescent labeling reagents for the postcolumn detection of organotin compounds has been reported.\(^{608,703,704}\) The FI observed after reaction of such flavones with organotin chlorides, i.e., triphenyltin, diphenyltin, monophenyltin, tributyltin, dibutyltin, trimethyltin, and tricyclohexyltin chloride, in the presence of micellar Triton X-100 was determined. The results indicated that morin and fisetin are the most general labeling agents for organotin species, with morin being the best reagent for mono-organotin compounds and fisetin the most sensitive for triphenyltin.\(^{608,704}\) The fluorescence of the flavonol complexes of mono- and diorganotin compounds was found to be greater in hexane as solvent than in the Triton X-100 system. However, the micellar system proved superior to hexane as a medium for the triorganotin complexes.\(^{608}\) The system has been employed for the fluorimetric detection of organotin compounds following their HPLC separation.\(^{703}\)

The fluorimetric method for determination of selenium based upon its reduction to selenite and subsequent reaction with 2,3-diaminonaphthalene to form the fluorescent 4,5-benzopiaselenol complex is enhanced in the presence of organized assemblies. For instance, the detection limit for Se in the presence of a CTAB micellar medium is 23.7 times lower than that observed in aqueous solution.\(^{705}\) Another report indicated that the FI of 4,5-benzopiaselenol was enhanced by a factor of 5–6 in the presence of either SDS micelles or β-CD.\(^{706}\) This enhancement factor increased to ca. 30 when the fluorescence was measured in a mixed SDS micelle–β-CD system relative to that observed in bulk water.

A few studies concerning the formation and fluorescent properties of metal chelates have been conducted in vesicle or liposome systems. In one study, the features of the Al\(^{3+}\)–8-quinoilinol-5-sulfonic acid chelate in the presence of cationic DODAB vesicles were evaluated.\(^{147}\) The fluorescence enhancement observed was similar to that seen in the presence of cationic CTAB micelles. However, in the case of the Al\(^{3+}\)–ferron chelate, the fluorescence signal observed in the presence of DODAB vesicles was greater than that in CTAB, Brij-35, or zwitterionic surfactant micellar media.\(^{151}\)

No fluorescence enhancements above that seen in aqueous solution were noted in the presence of CDs or anionic SDS micelles for this chelate. The proposed vesicle-enhanced method for Al(III) was validated by determining the aluminum content of different infant milk powders, with a detection limit of 4.0 ng mL\(^{-1}\).\(^{151}\) These results demonstrated that in some situations, a vesicle medium is superior to that of micelles or CDs and that vesicle aggregate systems can be utilized as a medium for developing more sensitive analytical methods for the determination of certain metal ions.

In addition to the determination of metal ion concentrations, different organic chelating agents have been employed for the determination of the concentration of cationic detergents, surfactants, or surface-active agents.\(^{707,708}\) For instance, the use of lumogallion has been reported for the fluorimetric determination of the cationic surfactants CPB and ethonium, with detection limits of 0.027 and 0.024 μg mL\(^{-1}\), respectively.\(^{707}\) The method is rapid and simple and does not require the use of an extraction step to remove the excess reagent as required in other spectral methods.

Several reports have considered the general mechanism and primary factors that influence the enhancement of the fluorescence of metal chelates by surfactant micelles.\(^{503,678,679,709,710}\) Solubilization and binding equilibria for reagents and metal chelates between the micelles and the aqueous phase seemed to be the most important factor governing the fluorescence enhancements observed for a number of metal ion–ligand chelates.\(^{503,679}\) The presence of the micellar surfactant can also alter the coordination number of the metal ion complex,\(^{711}\) which in some instances was postulated to be the reason for enhanced luminescence. There is a continuing need for comprehensive, mechanistic studies in this area. Perhaps studies reported in the physical chemistry literature could aid in this endeavor. For example, Demas and DeGraff reported on the binding interactions of a series of luminescent α-dimine complexes of ruthenium(II) and osmium(II) with SDS, Triton, and Brij micelles as studied by luminescence spectroscopy and quenching techniques.\(^{712–714}\) The strength of binding and degree of solvent shielding of the complexes by the micelles were found to correlate systematically with the charge and polarity of the complexes and the hydrophobicity of the coordinated ligands. The factors responsible for the enhancement of luminescence efficiency were also identified.

Micellar (or CD) enhancement of fluorescence quenching has been employed to determine some environmentally important metal ions. For example, in the
presence of the anionic micelle, NaLS, the fluorescence of the probe molecule naphthalene was efficiently quenched by metal ions thus allowing their quantification via Stern–Volmer calibration plots (with detection limits in the range of 1–10 \( \mu \)M). Likewise, quenching of 2,6-bis(benzoxazolyl)pyridine in a \( \beta \)-CD medium allowed the selective determination of the iron(III) ion.\(^{716}\) Anions can also be determined via micellar-amplified quenching. For example, as shown in Figure 8, the slope of the Stern–Volmer plot for the quenching of \( N \)-methylacridone by iodide ion in the presence of a cationic DTAC micelle medium is much greater (factor of ca. 11) than that observed in bulk aqueous solution alone, which translates into a lower limit of detection for the iodide ion.\(^{717}\)

A Triton X-100 micelle system containing the fluorescence pyrene molecule and the chelating agent dodecyl-dioxo-2,3,2 has been proposed as a sensor for transition-metal ions.\(^{718}\) The sensor action is based on the transition metal ion’s ability to quench the pyrene probe fluorescence.

### 3.2.4 Lanthanide- (or Ligand-) Sensitized Fluorescence in Organized Assemblies

The sensitization of the fluorescence of lanthanide and actinide ions by organic ligands is well known and has been extensively utilized during the past two decades in various analytical applications, including immunoassays, quantification of organic compounds, chromatographic detection schemes, etc.\(^{719–723}\) In particular, europium, terbium, samarium, and curium are known to form highly fluorescent chelates with a variety of organic ligands, often in the presence of a so-called synergistic agent. The intense sensitized fluorescence results from excitation of the organic ligand donor molecule, the energy of which is in part transferred (intramolecular energy transfer step) from its excited triplet (or singlet) state to the emitting level of the chelated lanthanide (or actinide) ion acceptor, resulting in ion-specific emission, and is characterized by large Stokes shifts, narrow (line-type) fluorescence bands, and long lifetimes. These properties allow spectral discrimination of the analytical signal and/or temporal time discrimination that eliminates (or greatly diminishes) background fluorescence and scattering signals and allows time-resolved signal accumulation such that very sensitive and selective fluorimetric methods can be developed. For a more detailed, quantitative discussion of this topic, the interested reader is referred to published review articles.\(^{719,720}\)

In some cases, an intermolecular energy transfer from the triplet level of an organic sensitizer directly to the unbound lanthanide ion has been reported.\(^{604,724}\) Such an intermolecular energy transfer process in a homogeneous solution is typically inefficient. However, intermolecular energy transfer from organic species to lanthanide ions in aqueous micellar solution has been observed.\(^{725,604,725}\) For instance, efficient energy transfer has been observed from SDS micellar solubilized naphthalene to terbium(III).\(^{725}\) Likewise, very efficient energy transfer from the 2-acetylnaphthalene triplet to Eu\(^{3+}\) was observed in SDS micellar solution.\(^{371}\) Such intermolecular energy transfer may be observed only by the use of organized media to bring the donor and acceptor molecules into close proximity and substantially increase their effective local concentrations.\(^{725,507,604,726}\) Since micelles solubilize the ternary complexes and can increase the efficiency of intermolecular energy transfer and also favorably impact luminescence parameters as previously described, they have been employed as enhancers in lanthanide-sensitized fluorescence assays. In particular, lanthanide ions exhibit low emission quantum yields in water. However, when complexed with appropriate ligands and solubilized in micellar media, intense, sharp emission bands are observed since the added agents help to “remove” water from the lanthanide ion’s primary solvation shell, thus preventing quenching of the excited state by water molecules.\(^{720}\) In addition, the fluorescence lifetimes of the lanthanide complexes are greater.\(^{727,728}\) For example, the lifetime of the europium chelate of thenoyltrifluoroacetonate (TTA) in ethanol was 180 \( \mu \)s, whereas it is 780 \( \mu \)s in the presence of Triton X-100 micelles and trioctylphosphine oxide (TOPO).

A comparative study of the fluorescence efficiency in the Eu\(^{3+}\)–TTA–TOPO chelate in ethanolic and aqueous Triton X-100 media has been conducted.\(^{728}\) It should be noted that large enhancements in the yield of intramolecular charge-transfer emission from organic molecules have also been observed in CD media.\(^{550}\) A comparative investigation on the effect of cationic micelles upon the fluorescence observed from the Eu\(^{3+}\) (and Tb\(^{3+}\)) complexes with Tiron, salicylic acid, acetylacetone, and 4-sulfonyl salicylic acid has been reported.\(^{729}\) Such lanthanide ion–organic
ligand–synergistic agent–micellar systems have been employed to determine the concentration of either the lanthanide–actinide ions or organic species that can act as ligands, as well as for time-resolved fluoroimmunoassays of a number of biological/clinical compounds.(719,720,731) In general, for determination of lanthanide or actinide ions, a sensitizer organic ligand (that can form a tris-chelate to the ion, such as a diketone (e.g. TTA)), is employed along with a strong donor ligand (synergistic agent), such as TOPO (or other organic phosphates, e.g. tributyl phosphate or sulfoxides), which can compete with water for inner coordination sites, and surfactant micelle.(732) This approach for the determination of lanthanides or actinides is termed ligand-sensitized fluorescence. The micelle system typically serves to solubilize the synergetic agents (as TOPO) and the ternary metal complexes in aqueous solution and enhances the fluorescence.(733–740) In addition, it has been postulated that the presence of the micellar medium alters the enol–ketone equilibrium ratio (ratio of ca. 0.016 in water and 20.0 in benzene) of the diketone (TTA) reagent so that the chelating properties of the enol form, which favors formation of the lanthanide–actinide chelate, predominate.(741) β-CD can also shift such keto–enol equilibria toward the enol tautomeric form(252); however, its use in such lanthanide-sensitized systems has apparently not yet been reported. The partition behavior of some Eu³⁺–diketone–TOPO adducts between nonionic surfactant micellar and bulk aqueous phases has been investigated.(742) The use of time-resolved laser-induced spectrofluorimetry has been employed for the study of uranium–surfactant micelle(743) and Eu³⁺–phospholipid vesicle(744) interactions. The fluorescence properties of terbium(III)–phospholipid complexes have been reported.(745) A thermodynamic study of the inclusion complexes formed between trivalent lanthanide ions and native CDs has been conducted.(747) The luminescent properties of the tris(dibenzoylmethane)europium(III) dihydrate–β-CD complex in the solid state have been reported.(746) It might prove interesting to examine the luminescent behavior of lanthanide ions and their diketone complexes in the presence of crown ether–based surfactant micelles. For example, the binding of Gd³⁺ to 1,4,7,10-tetraazacyclododecane-1-[1’-carboxy-1’-dodecyl(methyl)aminoxyethyl]-4,7,10-triacetic acid (DOTA) (CMC = 0.35 mM) has been examined in the context of its ability to function as a magnetic resonance imaging (MRI) contrast agent.(747) This system might prove to be interesting from the analytical luminescent viewpoint as well.

As for examples of the general utilization of this sensitized fluorescence technique, the determination of europium, terbium, and samarium ions was reported via use of TTA (or pivaloyl trifluoroacetone (PTA)) and TOPO in aqueous solution containing the nonionic surfactant nonaoxymethylene dodecyl ether (C₁₂E₉).(748–752) The stoichiometry and complex equilibrium involved with this system have been determined.(753) Europium(III) (λexc = 355 nm, λem = 615 nm) was determined in the 10⁻¹¹–10⁻⁵ M range with a detection limit of 6.0 × 10⁻¹² M via formation of the Eu(TTA)₃(TOPO)₂ complex in an aqueous Triton X-100 micellar medium.(734) For this system, the effectiveness of different nonionic surfactant micelles with respect to increasing the FI observed from this complex (or that of the corresponding Tb³⁺ complex) followed the order Triton X-100 > octylphenol ethoxylate (Triton) surfactants (OP) > Tween 80 systems.(740) Instead of the use of TTA or TOPO as the organic chelating and synergistic agents, a number of other organic ligands/agents have been proposed and evaluated.(732,753) Examples of such systems include TTA–phen–Triton X-100 (or Polysorbate 20), 2-naphthoyl trifluoroacetone (NTFA)–Triton X-100, sodium benzoate–Triton X-100, 2-benzoylindan-1,3-dione (BID)–Triton X-100, TTA–diphenylguanidine–Triton X-100, PTA–2,2′-bipyridine (BP)–Triton X-100, hexafluoracetylation (HFAC)–Triton X-100, trimesic acid (benzene-1,3,5-tricarboxylic acid)–Triton X-100, and benzoic acid derivatives–Triton (or EDTA)–CTAC among others. The fluorescence observed from Tb, Dy, or Eu using benzoate (or trimesic acid) as the chelating ligand in the presence of TOPO and Triton X-100 micelles was enhanced by almost 4 (or 3) orders of magnitude compared to the use of diketone ligands. With the lanthanide–benzoate–Triton X-100 system, the detection limits for lanthanides (Dy, Tb, Eu) were in the 10⁻⁹–10⁻¹⁰ M range.(735) A detection limit of 4.0 × 10⁻⁹ M Eu³⁺ was reported for the BID–Triton X-100 system.(763) In addition to use of Triton X-100, the nonionic surfactant Tween 20 has also been employed as the micellar entity. A detection limit of 50 ppt Dy³⁺ was reported for the TTA–Triton–TWEEN 20 system,(762) Dysprosium(III) ion was determined at concentrations as low as 1.0 × 10⁻⁹ M using the EDTA–Tiron–CTAB system.(764) The fluorescence signal observed in this system was ca. 12.3 times greater in the CTAB (or cetyltrimethyl ammonium chloride) micellar systems than that observed for Triton X-100.(763) A detection limit of 20 pM Tb³⁺ was reported via use of an unoptimized 1,1,1-trifluoro-2,4,3-tridecanedione (TFTD) or 1,1,1-trifluoro-5,5-dimethyl-2,4-hexanedione (TFDMH)–Triton X-100 system.(732) Terbium (III) has also been determined via use of the PTA–TOPO–C₁₂E₉ system in the flow injection mode with a detection limit of 16 ng mL⁻¹.(764) Tb³⁺ was also determined down to the 0.003 ng mL⁻¹ level.
using the system Tiron–imidodiacetic acid–CTAB.\textsuperscript{(739)} Determination of curium at the 0.10 ng mL\(^{-1}\) level in a micellar medium by this approach has been reported.\textsuperscript{(743)} Thulium(III) and yttrium(III) were determined down to 1.0 \(\times\) \(10^{-7}\) M and 1.8 nm L\(^{-1}\), respectively, using the system bis(1-phenyl-3'-methyl-5'-pyrazol-4'-one)hexanedione–CTAB.\textsuperscript{(781, 785)} The presence of the CTAB enhanced the FL of these \(\text{Tb}^{3+}\) and \(\text{Y}^{3+}\) chelates by a factor of ca. 25 and 8, respectively. Curium(III) has been determined at the 0.10 ng L\(^{-1}\) (5 \(\times\) \(10^{-13}\) M) concentration level using the TTA–TOPO–Triton X-100 system.\textsuperscript{(629)} The fluorescence observed from the ytterbium(III)–(2-pyridylazo)resorcinol–CTAB (or CPB or chloride) system was 2.8–4.5 times greater than in the absence of the cationic CTAB or cetylpyridinium salt surfactant media.\textsuperscript{(749)} This enhancement was attributed to the greater rigidity of the micellar bound complex.

Hence these assays are superior to the traditional solvent extraction methods that have been employed for determination of these lanthanide/actinide ions, in terms of not only their simplicity and speed, but also their sensitivity.\textsuperscript{(758)} It has been reported that the presence of certain other ions, such as La, Gd, Lu, or Y, can lead to additional enhancements of the fluorescence observed from the chelates of Tb, Eu, and Dy. This is referred to as the \textit{columinescence} (or \textit{cofluorescence}) effect (Xu et al.\textsuperscript{(786)} have reviewed this topic). This effect is based on an intermolecular energy transfer from the chelates of the enhancing ion (such as Gd\(^{3+}\) or Tb\(^{3+}\)) to the chelates of the emitting ion (such as Eu\(^{3+}\) or Sm\(^{3+}\)).\textsuperscript{(766)} Fluorescence enhancement of rare earths due to columinescence has been reported using \(\beta\)-diketone ligands as the energy transfer agent along with TOPO or BP as synergistic ligands and Triton X-100 micelles.\textsuperscript{(758)} Detection limits for Eu\(^{3+}\), Th\(^{3+}\), and Sm\(^{3+}\) were reported as 0.019, 0.27, and 3.8 pM, respectively, for the PTA–BP–Triton X-100 system containing added yttrium(III) cation.\textsuperscript{(758)} These detection limits were slightly better than those reported for the PTA–phen–Triton X-100 system with added Y\(^{3+}\) for these three metal ions.\textsuperscript{(767)} The addition of gadolinium(III) to the system containing samarium or europium(III) ions with TTA–phen–Triton X-100 resulted in 1–2 orders of magnitude greater sensitivity for the determination of Sm\(^{3+}\) or Eu\(^{3+}\) compared to that observed in its absence.\textsuperscript{(768)} The specific detection limits reported were (5.0–7.5) \(\times\) \(10^{-10}\) M for samarium and 7.5 \(\times\) \(10^{-12}\) M for europium.\textsuperscript{(769, 770)} Substitution of 4,7-diphenyl-1,10-phenanthroline for phen in this general system led to a detection level of 0.6 pg mL\(^{-1}\) for Eu\(^{3+}\).\textsuperscript{(771)} A detection limit of 10 pM for Eu\(^{3+}\) was reported for the system TTA–phen–Triton X-100 in the presence of Lu(III).\textsuperscript{(772)} Use of the TTA–TOPO–CTAB system with added gadolinium(III) allowed the determination of europium(III) with a detection limit of 8.0 \(\times\) \(10^{-11}\) M.\textsuperscript{(737)} A slightly more sensitive method (detection limit 2.6 \(\times\) \(10^{-11}\) M) for europium(III) was achieved using the system dibenzooylmethane (DBM)–CPC in the presence of Gd\(^{3+}\) and triethanolamine.\textsuperscript{(773)} A detection limit of 3.0 \(\times\) \(10^{-12}\) M Eu\(^{3+}\) was reported for the diphacineone [2-(diphenylacetyl)indan-1,3-dione]–ammonia–Triton X-100 system containing La\(^{3+}\) ion.\textsuperscript{(016)} Using the TTA–CTAB–Triton X-100 system in conjunction with Gd\(^{3+}\) also allowed the determination of Eu(III) with a reported detection limit of 2.0 \(\times\) \(10^{-12}\) M.\textsuperscript{(758)} Detection limits of 4–15 fM were reported for the TTA (or benzoyl trifluoroacetone (BTA))–phen–Triton X-100 system containing added yttrium(III) ion.\textsuperscript{(774)} In the determination of europium(III) via use of the TTA–phen–surfactant system containing terbium(III), the relative luminescence intensity as a function of the specific surfactant micelle system followed the order Triton X-100 > Tween 20 > polyoxyethylene lauryl ether > SDDBS > CTAB > CPC.\textsuperscript{(754)} Under optimized conditions using Triton X-100 micellar media, a detection limit of 1.0 \(\times\) \(10^{-13}\) M Eu(III) was reported.\textsuperscript{(754)} The use of mixed ligand complexes of TTA and 1,10-diaza-15-crown-5 in the presence of CTAB and Gd\(^{3+}\) (or other lanthanides) also allowed the determination of ppb levels of Eu(III).\textsuperscript{(775)} The reagents Y\(^{3+}\)–TTA–CTAB and Y\(^{3+}\)–sparfloxacin–SDS were utilized to determine Eu\(^{3+}\), with a detection limit of 1.0 \(\times\) \(10^{-11}\) M and 1.0 \(\times\) \(10^{-13}\) M, respectively. A similar detection limit for Eu(III) was reported for the reagent system composed of Gd\(^{3+}\)–ofloxacin–sodium dodecylbenzenesulfate micelles.\textsuperscript{(730)} The presence of the Triton X-100 or CTAB micelles in these reagent combinations was thought to enhance the intercalate energy transfer, protect the chelates against the quenching effects of water molecules, and stabilize the fluorescence in such systems.\textsuperscript{(737, 754, 758, 766, 768)} Cationic surfactants can function as a cation in the ternary complex that forms in some instances.\textsuperscript{(738, 778)} Typically, there is an optimum surfactant concentration beyond which further increases in concentration lead to decreased fluorescence. This is the result of dilution of the system with increasing micelle concentration so that the probability that both donor chelate species and acceptor fluorescent species are bound to the \textit{same} micelle is decreased.\textsuperscript{(756)} Separation of the donor and acceptor in different micelles obviously decreases the efficiency of the intermolecular energy transfer step with a resultant diminution in the FL.

To the best of our knowledge, there are no reports concerning the examination of such systems for the determination of lanthanides/actinides in the presence of CD or vesicle organized assemblies. However, enhanced fluorescence was observed for Eu\(^{3+}\)–TTA–phen in the
presence of Tb$^{3+}$ (or Gd$^{3+}$)–TTA–phen when confined in Langmuir–Blodgett films. In addition, there is one report concerning the synthesis of polymerized fluorescent liposomes that incorporate lanthanide ions.

Energy transfer from an organic compound to the lanthanide ion can also be utilized to improve the fluorimetric determination of organic analytes that can chelate the metal ion. This approach for assaying organic components is referred to as lanthanide-sensitized luminescence (for a review see Georges). A number of reports indicate that the presence of micelles can further intensify the luminescence intensity of such systems and improve the sensitivity. Methyl anthranilate in food samples, after hydrolysis to $o$-aminobenzoic acid, was determined by the sensitized luminescence obtained from the Tb$^{3+}$–TOPO–aminobenzoic complex in the presence of TX-100. This approach was applied with success for analysis of methyl anthranilate and adenosine triphosphate (ATP) in a variety of food and drink samples. The antibiotics ciprofloxacin, enrofloxacin, and levofloxacin have also been determined via terbium-sensitized luminescence in the presence of SDS micelles or sensitized fluorescence of europium in the presence of 1,10-phenanthroline in SDBS micelles. Tetraacyclines (such as doxycycline, oxytetracycline, demeclocycline, methacycline, and chlortetacycline) have been determined using europium-sensitized fluorescence with EDTA as a coligand in the presence of CTAC micelles.

Table 9 summarizes other representative applications of the lanthanide-sensitized luminescence for the determination of organic compounds in the presence of TX-100.

a Also referred to as MECC, micellar enhanced capillary chromatography.
b Micellar liquid chromatography, which employed aqueous solutions of surfactant micelles as the mobile phase.
surfactant micellar media. Detection limits for the determination of the PAHs anthracene, pyrene, and benzo[k]fluoranthene, pyrene, and benzo[ghi]perylene were in the range 0.021–0.70 nM in the Tb\textsuperscript{3+}–NaTC system.\textsuperscript{(121,786)} As noted by Georges, the application of this general method is not limited to the examples just mentioned or shown in Table 9, but is also potentially valid for many other organic species, provided that they exhibit large molar absorptivities and have the ability to function as energy donors with respect to a lanthanide ion.\textsuperscript{(719,787)}

More recently, quenching of lanthanide complexes in micelles has been utilized to determine the quencher concentration. Addition of ATP to the Eu(III)/Gd(III) complex with TTA in nonionic Brij-35 micelles diminished the observed luminescence from this complex and allowed the determination of ATP (detection limit 8.0 × 10\textsuperscript{-8} M) in fruit juice samples.\textsuperscript{(782)}

Amino- and mercapto-containing compounds have been detected following HPLC separation using lanthanide-sensitized fluorescence.\textsuperscript{(111)} In this detection scheme, a precolumn derivatization method was employed in which the amino compounds were reacted with the Eu\textsuperscript{3+} chelate of N-(p-isothiocyanatobenzyl) diethylenetriaminetetraacetic acid (IDTTA) (or Eu\textsuperscript{3+} chelate of 1-{[5-maleimidopenyl-toly]carbonyl]amino} benzyl)ethylenediaminetetraacetic acid (MEDTA) in the case of thiols) and resolved via reversed-phase HPLC. Next, a postcolumn derivatization step is conducted in which the labeled Eu–IDTTA–amino compounds (or Eu–MEDTA–thiols) are reacted with the reagent NTFA–TOPO–Triton X-100, which results in formation of the highly fluorescent Eu\textsuperscript{3+}–NTFA–TOPO chelate. For thiols, the detection limits reported ranged from 13.2 to 18.8 fmol.\textsuperscript{(111)} The presence of Triton X-100 micelles was necessary for observation of enhanced fluorescence. Terbium-sensitized fluorescence was utilized as a detection mode in HPLC for 14 different steroidal hormones which were eluted with an SDS-containing mobile phase (detection limits ranged from 0.08 to 0.55 μg mL\textsuperscript{-1}).\textsuperscript{(788)} Use of Eu\textsuperscript{3+}–TOPO–Triton X-100 (pH 10.5) as a postcolumn derivatization reagent allowed the sensitive time-resolved sensitized luminescence detection of tetracyclines following their HPLC separation.\textsuperscript{(789)} Use of Tb\textsuperscript{3+}–CTAB allowed the sensitive fluorimetric determination of 2,6-dihydroxyypyrimidine-4-carboxylic acid following capillary electrophoretic separation using CTAB in the run buffer.\textsuperscript{(619)} This method required no sample pretreatment and was free of any known interference in the urine samples examined. Micellar HPLC with SDS mobile phases in conjunction with sensitized terbium fluorescence detection allowed the development of a superior analytical method for semiquinoid steroids.\textsuperscript{(790)} The method was sensitive, selective and simple, and allowed the direct injection of urine on to the column without the need for any sample preparation step.

Numerous reports concerning the dissociated enhanced lanthanide fluoroimmunoassay (DELFIA) technique for determination of clinical/biological analytes have appeared in the clinical/medical literature (reviews are available).\textsuperscript{(791–796)} The DELFIA technique was based on the work of Hemmila et al. DELFIA involves the use of an immunocomponent (antibody, etc.) labeled with a lanthanide metal (i.e. Eu\textsuperscript{3+} or Sm\textsuperscript{3+}) chelate which is nonfluorescent. Typically, the binding of the lanthanide(III) ion to an immunoreactive component is accomplished via use of polycarboxylic derivatives (EDTA, glycol-bis(2-aminoethylether)-N,N,N',N'–tetraacetic acid (EGTA), diethylenetriaminopentaacetic acid (DTPA)) that contain a suitable functional group required for covalent coupling. Such polycarboxylates have very large lanthanide ion–binding constants, but are strongly pH dependent. The immunoassay can be conducted as either a noncompetitive or competitive reaction in a solid-phase system. The amount of immunconjugate is determined by dissociation of the lanthanide ion from the immunocomponent on the solid phase. This is accomplished by lowering the pH (pH < 4.0, which lowers the stability of the chelate complex) with the dissociated lanthanide ion going into an aqueous solution that contains the “enhancement agents” (i.e. β-diketone or other sensitizer, synergistic agents such as TOPO, and micelle-forming surfactant). The enhancement agents greatly intensify the fluorescence as previously noted, and in DELFIA, time-resolved intensity measurements are made to eliminate noise and increase sensitivity.\textsuperscript{(720,791)} In such systems, the label may be detected in concentrations as low as 10\textsuperscript{-17} mol of Eu\textsuperscript{3+} per microtitration well.\textsuperscript{(797)} The general system has been successfully applied for the assay of the following analytes in human serum: cortisol, thyroxine, α-fetoprotein, ferritin, thyrotropin, prolactin, lutropin, chorionic gonadotropin, follitropin, progesterone, carcinoembryonic antigen, and rubella IgG and IgM antibodies.\textsuperscript{(690,720,758,774,791,798–801)} Among many others. Sensitive cytotoxicity assays using DELFIA with Eu–DTPA have been developed.\textsuperscript{(801)} The utilization of chelated terbium as a label in fluorescence immunoassays has also been reported.\textsuperscript{(802,803)} The cofluorescence enhancement systems are also suited for use in double (or multi) label time-resolved fluorimetric
immunoassays,\textsuperscript{720,758,766,767,774} A review of the cofluorescence effect as it pertains to time-resolved fluoroimmunoassays is available.\textsuperscript{766}

More recently, liposomes have been employed in steady-state and time-resolved fluoroimmunoassays for clinical/biological analytes.\textsuperscript{804–808} Liposomes can incorporate fluorescent labels (including fluorescent lanthanide chelates), either encapsulated within their inner aqueous region (polar species) or embedded in the lipid membrane (nonpolar or amphiphilic species). In an assay dubbed “complement immunolysis”, recognition of an analyte by an antibody (or other species) triggers the release of thousands of reporter molecules which are subsequently detected by fluorescence (or other means).\textsuperscript{804} The large number of molecules released thus provides substantial amplification of the original antibody recognition event.\textsuperscript{805} Such encapsulated contents can also be released upon lysis of the liposomes and the assays developed in the usual manner as in DELFIA protocols. Haptens have been determined via this approach.\textsuperscript{808}

4 SOME GENERAL EXPERIMENTAL CONSIDERATIONS

The chemicals required for the preparation of the organized assembly systems are all commercially available. Cognizance should be taken of the purity of the surfactant or CD preparations utilized to prepare the solutions required for analytical luminescence applications. Although highly purified CDs do not fluoresce, some less purified formulations sometimes contain fluorescence impurities due to the preparation scheme employed in their purification. This is probably the cause of some reports in the analytical literature which note that CDs are strongly fluorescent,\textsuperscript{107,108} or quench fluorescent solutes.\textsuperscript{809} In addition, the presence of fluorescent impurities in commercial nonionic and some cationic surfactant preparations has been noted.\textsuperscript{455,686} Weak fluorescence from NaDC solutions has also been reported when a He–Cd laser was employed as the excitation source.\textsuperscript{564} Quenching impurities in other commercial preparations have also been reported.\textsuperscript{1178} In particular, peroxides can be present in nonionic surfactant preparations.\textsuperscript{860} The presence of quenching impurities in the preparations can have severe detrimental effects upon the desired fluorescence measurement. Purification procedures for various surfactants and CDs are available in the literature.\textsuperscript{1395,660,810} In addition, high-purity commercial preparations are now available for many of the surfactants or CDs required in flurometric applications. However, there are still some recent reports that note that while CDs and surfactant micelles elicit strong enhancing effects on analyte fluorescence emission, the relative standard deviations were quite high “likely the result of intense signals given by the [organized assembly] blanks” which precluded their use in the desired fluorescent method.\textsuperscript{981}

Also, for most applications, care should be taken to avoid the use of organized assembly materials that are themselves inherently fluorescent. For example, surfactants containing an aromatic ring, such as the Tritons, Igepals, Nonidets, alkylpyridinium salts, alkylbenzenesulfonates (e.g. SDDBS), and benzyltrimethylhexadecy lammonium halides, should probably be avoided since their use could give rise to high background fluorescence at the desired analytical emission wavelengths.\textsuperscript{107,453,812} In addition, the pyridinium surfactants can act as potent quenchers toward many organic analytes.\textsuperscript{107,335} The reduced forms (nonaromatic ring system) of some of these materials, such as reduced Triton X-100, are commercially available, but are more expensive.

Some surfactant micelles, such as CTAB, SDS, and Tergitol XD, present solution preparation difficulties.\textsuperscript{220,453} That is, the preparation of the more concentrated stock solutions of such surfactants requires warming/heating the solution in order to ensure complete dissolution of the solid surfactant material.\textsuperscript{220,604,628,879,813} Surfactants such as CTAB, TDSS, and sodium hexadecylsulfate have Krafft points that are well above room temperature. For instance, the Krafft point of SDS is ca. 16–23 °C.\textsuperscript{1180,220} Thus, when using such surfactant micelle systems, the luminescence measurements have to be conducted at an appropriate temperature (i.e. experimental temperature above the Krafft temperature) in order to prevent precipitation of the surfactant. Alternatively, it is often more convenient to utilize other micelle-forming surfactants to produce the same desired effects. For instance, CTAB has a Krafft temperature of ca. 17–20 °C, whereas that of CTAC is ca. 11 °C.\textsuperscript{1180,618} Hence CTAC is preferred to CTAB (which also has the bromide ion which can quench excited states of some organic species).

It should be mentioned that heating the aqueous solutions of some nonionic surfactant solutions can lead to phase separation (CP) behavior, where the surfactant-rich phase separates from the bulk aqueous (surfactant-depleted) phase.\textsuperscript{659,660} The CP temperatures for typical nonionic surfactant solutions have been compiled.\textsuperscript{859} In order to avoid complications from such phase separation, as has been reported in the literature,\textsuperscript{814} one should utilize such surfactant micelle solutions at a temperature well below their usual CP temperature. Materials that are toxic, such as the surfactant myristylammonium bromide, should be avoided.\textsuperscript{453} Surfactants containing heavy-atom counterions (such as Br or I) or other moieties (such as pyridinium ion) could quench certain organic molecules’ excited states. Hence this fact should
be taken into account for surfactants such as CTAB, tetracycltrimethylammonium bromide (TDAB), and alkylpyridinium salts.\(^\text{[249,588,813]}\)

Whereas the solubilities of \(\alpha\)- and \(\gamma\)-CD are ca. 14.5 and 23.2 g per 100 mL in water, respectively, that of \(\beta\)-CD is only 1.85 g per 100 mL.\(^\text{[161]}\) Thus, when employing \(\beta\)-CD in fluorescence measurements, it is sometimes not possible to achieve the proper (high) concentrations required to produce maximum benefits.\(^\text{[180]}\) In such cases, the use of \(\beta\)-CD derivatives that are much more soluble in water, such as hydroxypropyl or methylated \(\beta\)-CDs, or aqueous urea solutions, which serve to solubilize the \(\beta\)-CD, is recommended.\(^\text{[180,815]}\) Alternatively, water–cosolvent mixtures can be employed in order to increase the \(\beta\)-CD concentration.\(^\text{[816]}\) When utilizing CD media in analytical derivatization reactions under basic conditions, cognizance should be made of the ability of CDs to catalyze hydrolysis reactions which might interfere with the desired analytical reaction.\(^\text{[817]}\) Degradation of organized assemblies on storage can lead to unexpected behavior in use, and perhaps give rise to misleading interpretation of results.\(^\text{[94]}\) In this regard, it should be recognized that some organized assembly media, such as the CDs and anionic alkylsulfate surfactants, are susceptible to acid-catalyzed hydrolysis, particularly when heated or subjected to long-term storage under very acidic conditions.\(^\text{[94,160,161,385,818]}\) Hence stock solutions of such organized media should not be stored for a long time under very acidic conditions. Under very basic conditions, CDs can ionize (the \(pK_a\) of their hydroxyl groups is in the range 12.0–12.4).\(^\text{[160,277]}\) Nonionic surfactants can form peroxides during storage. Some commercial formulations have added oxidizing agents present,\(^\text{[94]}\) which might also interfere with fluorescence measurements.

Experimental protocols for the preparation of solutions required for the determination of fluorescence enhancement factors in the presence of an organized assembly system relative to that in a bulk solvent have been proposed.\(^\text{[206,819]}\) Differences in some of the fluorescence parameters have been noted depending upon how the solute solutions are prepared (i.e. mixing via ultrasonication vs stirring of the solutions).\(^\text{[180]}\) For fluorescence measurements in all organized assembly systems, appropriate background (reference) solutions should be prepared without the analyte molecule present in order to correct for possible contributions of light scattering to the observed analytical signal.\(^\text{[571,820]}\) In some cases, the appropriate use of filters can minimize the effect of scattered light.\(^\text{[820]}\) However, for reproducible results, it is probably best if the precautions that have been recommended in papers concerning basic investigations of such systems also be employed in their use in chemical analysis applications. For instance, vesicle solutions should be prepared and used within 24–48 h of their preparation, with storage in the dark under \(N_2\) at 4 °C when not in use.\(^\text{[198,295,821]}\) Care should be taken during all vesicle preparation steps to avoid undue exposure to light.\(^\text{[198,339,508,821]}\) In many instances, proper “aging” (equilibration) of vesicle analyte–containing solutions is required in order to obtain reproducible spectral data.\(^\text{[148]}\) Depending on the conditions and additives present, some liposome-containing systems can undergo time-dependent fusion with resultant formation of larger vesicle membranes (see Figure 9).\(^\text{[150,153,822,823]}\) Deliberately keeping the amphiphile concentration as low as possible minimizes such fusion.\(^\text{[824]}\) Fluorescence techniques are available to monitor the time course of vesicle fusion.\(^\text{[150,822,825]}\) Thus, the best reproducibility is typically obtained in analytical applications by using vesicle/liposome systems of the same “age”. Greater fluorescence enhancements are typically observed in vesicle/liposome media when the measurements are conducted at a temperature below the phase transition temperature (\(T_M\)) also referred to as the crystal-to-liquid crystal temperature.\(^\text{[148]}\) Likewise, some aging effects have been reported for micellar solutions.\(^\text{[190,826–828]}\) Hence, in many studies, aqueous stock solutions were always prepared fresh daily or utilized within a specified time frame in order to avoid errors due to such aging and allow time for equilibration of reagents within the organized assembly system.\(^\text{[95,423,454,813,826]}\)

In many instances, it is necessary to bubble nitrogen through the organized assembly solutions in order to displace oxygen so as to avoid its quenching effect upon some analytes\(^\text{[75]}\) or the possibility of undesired photooxidation reactions.\(^\text{[385]}\) For example, the FI of the analytes benzo[ghi]perylene, chrysene, benzo[g,h,i]perylene and perylene in oxygen-free solutions are 2.9, 2.7, 6.4, and

![Figure 9](image-url) Oversimplified diagram (cartoon) illustrating the vesicle–vesicle fusion process which results in the formation of a larger aggregate entity with decreased membrane curvature and an increase in the hydrophobic to hydrophilic surface ratio.

9.0 times greater, respectively, than those observed in oxygenated solution.\textsuperscript{829} Oxygen is ca. 20 times more soluble in air-saturated alkane solvents than in water.\textsuperscript{364} In fact, the solubility of oxygen in water is only ca. 1\% (by mass) of that observed in hydrocarbon solvents.\textsuperscript{713} The oxygen concentration at 25°C in micellar CTAB, SDS, and Tweens was reported to be ca. 0.13, 0.12, and 0.13–0.23 mM, respectively,\textsuperscript{830} whereas that in solutions of sodium octanoate ranged from 1.28 to 1.57 mol O\textsubscript{2} per atmosphere in 1000 g of H\textsubscript{2}O.\textsuperscript{831} Another report indicated the oxygen solubility in water as 1.41 mM, whereas that in SDS was 1.47 mM; in another, the water solubility of oxygen was reported as 0.265 mM and in SUV vesicles as 0.85 mM.\textsuperscript{713} The solubility of atmospheric oxygen in water in the presence of several anionic surfactants at different temperatures and surfactant concentrations has been reported.\textsuperscript{832} The solubility of oxygen in common solvents (such as water, alcohols or cyclohexane) at 25°C and 1 atm has been compiled.\textsuperscript{833}

One problem with the use of surfactant or micellar solutions arises when deoxygenation by purging with an inert gas is required, that is, the problem of foam formation and frothing, which makes such degassing problematic and cumbersome. Several approaches have been employed to overcome this difficulty. For instance, a simple gas bubbling system for removal of dissolved oxygen in surfactant and micellar solutions has been described.\textsuperscript{834} This cell allows a continuous, rapid flow of a purge gas through such solutions without loss of fluid in spite of severe foaming. Using this cell, the oxygen concentration was reduced to a negligible value (<10\textsuperscript{−5} M) in about 13 min.\textsuperscript{834} A very similar cell system has also been described by other workers to minimize foam losses during deaeration.\textsuperscript{835}

Alternatively, in situ chemical deoxygenation can be employed.\textsuperscript{836} For instance, sulfitone has been utilized as an oxygen scavenger in anionic micellar\textsuperscript{836} or CD\textsuperscript{837} solutions. This method is based on the redox reaction shown in Equation (9):

\[
\text{O}_2(g) + 2\text{SO}_3^{2−} (aq) ⇌ 2\text{SO}_4^{2−} (aq) \quad (9)
\]

This approach is rapid (requiring about 12–15-min reaction time), convenient, precise, and superior to the solution nitrogen purging technique.\textsuperscript{838} In particular, this deoxygenation procedure has been employed in the context of micelle- (or CD)-stabilized room-temperature phosphorescence\textsuperscript{836,837} (see Phosphorescence Measurements, Applications of) as well as in applications of terbium-sensitized luminescence applications.\textsuperscript{783} However, it has been cautioned that addition of sulfite to some micelle systems, such as SDS containing thallium(I), can result in the formation of a metal–sulfite complex which absorbs radiation below 275 nm.\textsuperscript{838} Therefore, in applications involving the determination of metal ions in which this deoxygenation scheme is employed, experiments should first be conducted to ensure that such a metal–sulfite complex does not form or, if formed, that the resulting complex does not absorb appreciably at the required fluorescence excitation wavelength.

Another effective means of degassing solutions of organized media is through multiple freeze–pump–thaw cycles on a high-vacuum line to avoid the effects of traces of oxygen.\textsuperscript{839,840} However, such vacuum degassing is not very convenient and requires a vacuum line system, etc. In addition, vacuum degassing micelle solutions are not significantly better than nitrogen purging as a means of deoxygenation as gauged from fluorescence probe studies.\textsuperscript{840} However, there are some reports that note that the nitrogen bubbling technique for removal of oxygen from solutions does not eliminate all traces of the O\textsubscript{2}(g), with an estimated 2 μM residual oxygen gas still present following such purging.\textsuperscript{502,686}

Lastly, the use of an automated sample deoxygenation system might also be applicable to solutions containing some of the organized assembly systems.\textsuperscript{840} Two reports provide a nice survey of current methods employed for deoxygenization of solutions along with their advantages, limitations, and analytical applications.\textsuperscript{841,842}

It should be noted that freshly prepared aqueous solutions of some organic solutes in the absence and presence of CDs appear to be unstable when the solutions are exposed to the atmosphere and/or bubbled by air or nitrogen gas.\textsuperscript{843} Repeated bubbling–freezing–thawing cycles enhance the effect.

The preparation of required concentrated stock solutions of analytes in aqueous organized assembly solutions is sometimes problematic owing to extremely low solute solubilities or slow dissolution rates.\textsuperscript{363,844} In many such cases, the following general protocol has been employed: (i) initially prepare a concentrated analyte stock solution in a water-miscible organic solvent (alcohol, acetone, tetrahydrofuran, etc.) in which it is soluble, (ii) then add a small aliquot of this concentrated solution to the aqueous organized assembly solution (typically strive to keep the percentage of the organic cosolvent under 0.5\% (v/v)), (iii) next, purge the resulting organized assembly solution with nitrogen or argon in order to remove/displace the small amount of organic solvent present, and (iv) lastly, add an appropriate amount of water to this solution to compensate for evaporation.\textsuperscript{194,363,844} Alternatively, the purge step can be skipped provided all analytical fluorescence measurements are conducted on standard and unknown solutions that contain the same amount of organic cosolvent. While this procedure is successful in most instances, for some solutes it results in the
formation of microcrystals of the analyte, and these can be a source of artifacts, since their resulting solutions can scatter light and/or give rise to strong excimer emission.\textsuperscript{194,844}

Some of the preparation recipes for formation of SUV systems require the presence of small amounts of an organic solvent (typically chloroform, which is a potential fluorescence quencher as well). Thus, nitrogen purging is sometimes also utilized to remove traces of such organic solvents.\textsuperscript{511,515}

Recall that the presence of organic cosolvents can preclude (or alter) surfactant micelle formation. Thus, if such cosolvents are utilized in the preparation of solutions, they should be present at low concentrations (final percentage $<1.0\%$ (v/v)).\textsuperscript{385} Such a low organic cosolvent concentration serves to minimize the perturbation to the surfactant aggregate structure. As previously noted, bile salt surfactant systems can tolerate greater amounts of such organic additives than the classic surfactant micelle-forming systems.

As noted, when manipulating (pipetting, shaking to mix, etc.) aqueous surfactant micelle solutions, bubble (foam) formation can cause difficulties (such as when trying to add water to dilute to the mark of volumetric glassware). It has been noted that when working with such surfactant solutions in the laboratory, they can be freed of bubbles by placing the container in an ultrasonic bath filled with water. Apparently, after only a few seconds of exposure to ultrasound, clear, bubble-free solutions are obtained.\textsuperscript{845} In one reported application, 15 min of this type of ultrasonic “stirring” was employed to remove air bubbles.\textsuperscript{670}

As has been cautioned in the literature by others, care should be exercised with respect to the type of electrodes employed and the meaning of any pH measurements made in micellar- (or vesicle)-containing solutions.\textsuperscript{846}

The interested reader is referred to any number of published applications for more detailed experimental protocols and the different experimental variables that can impact the fluorescence signal when utilizing different organized assemblies in fluorescence methods.\textsuperscript{711,847–878}

5 CONCLUSIONS

In contrast to the situation in the mid-1980s, when the use of organized assemblies in analytical fluorimetry was still largely unexplored,\textsuperscript{20} this is now an established practice in chemical analysis. The reported advantages in terms of the ability to control solubility, reactivity, sensitivity, and, to a lesser degree, selectivity by the judicious choice and use of an organized assembly system is the reason for the popularity and success of organized assembly–enhanced fluorescence measurements. Future research should be directed toward increased use of these systems in rate/kinetic methods of analysis, development of functionalized ordered media which target a specific analyte of interest, and different means by which to immobilize the surfactant micelle-vesicle systems. Development of such materials that mimic their properties will serve to extend the scope of possible applications. Some trends in this field have been noted in a review article.\textsuperscript{879} In particular, the utilization of “designer” surfactant and CD media for application as specific fluorescent sensors is becoming very popular.\textsuperscript{164,165,173,880–882} The use of surfactant-mediated CP extraction (for preconcentration of the analyte) combined with fluorescence enhancement should lead to the development of ultratrace methods. An overlooked but very beneficial application concerns the utilization of these aqueous organized media to enhance sample preservation and long-term storage of environmental and biological samples, in the context of not only fluorescence measurements but chemical analysis in general.

ACKNOWLEDGMENTS

This chapter is dedicated to late Prof. Janos H. Fendler for his pioneering research and development of the general field of organized assemblies and membrane mimetic chemistry. We thank our coworkers, whose names appear in the references listed, for their dedicated and enthusiastic contributions to our work cited in this review. Many thanks are due to Prof. Frank H. Quina (Instituto de Quimica, Universidad de Sao Paulo, Brazil) for his careful reading of the proofs and helpful comments in the preparation of this article. In addition, we thank an anonymous referee for helpful comments regarding the improvement of this manuscript as well as for providing additional useful citations. Acknowledgment is also made to the donors of the Petroleum Research Fund, administered by the American Chemical Society, Pharmatec, Inc. (Alachua, FL) and Wake Forest University (through a Research and Publication Fund Grant) for providing financial support for our own work in this research area. This article was written while one of us (W. L. Hinze) was supported by a Wake Forest University Reynolds Research Leave. Additionally, N. Memon and A. Balouch gratefully acknowledge the Higher Education Commission of Pakistan and NCEAC (University of Sindh, Jamshoro, Pakistan) for their support of this work and granting of a study leave during their time at Wake Forest University.

Over the years, the emissive characteristics (spectral, temporal, and polarization) of fluorophores have been widely used to probe the local environments of fluorescent centers. Fluorescence lifetime and rotational reorientation time measurements, in particular, offer a means to elucidate subtle features when examining, for example, complex systems involving environmental heterogeneity, energy transfer, quenching pathways, or excited state reactions. Further, because fluorescence occurs on the nanosecond ($10^{-9}$ s) timescale, competing or perturbing kinetic processes like collisional quenching, solvent relaxation, energy transfer, and rotational reorientation can affect the fluorescence. Thus, a carefully chosen fluorophore can serve as an internal nanosecond or faster stopwatch of environmental fluctuations.

This article is divided into a brief introduction, a short discussion on instrumentation, and several sections on various applications of excited state fluorescence measurements.

1 INTRODUCTION

During the last few decades, fluorescence spectroscopy has developed into an important and widely used technique in the biological, chemical, and physical sciences. Multidimensional in nature, fluorescence is characterized by several parameters, most notably the excitation and emission wavelengths, the steady state polarization or anisotropy, the excited state lifetime, and the rotational reorientation time.$^{[1–16]}$ Of these, the latter two reflect the time course of the emission process; therefore, it is often of interest to determine such time-dependent emission from samples. This arises because the fluorescence anisotropy and/or intensity decay kinetics are usually characteristic of the system under investigation.$^{[1–16]}$ In condensed phase systems, these two processes typically occur in $10^{-8}–10^{-13}$ s. As a result, any process which occurs on a similar timescale can potentially perturb the fluorescence. For example, phenomena like collisional quenching, energy transfer, solvent relaxation, and rotational reorientation all occur on the fluorescence timescale. Hence an excited state fluorophore can be used to report on its local environment as well as temporal changes in the environment. Consequently, this information provides insight into important processes occurring on the nanosecond and subnanosecond timescale. For example, the presence of two fluorescent tryptophan residues within a protein, each of which resides in a distinct physicochemical environment, may manifest itself in the recovery of two apparent decay rates, as has been observed by Ross et al.$^{[2]}$ for liver alcohol dehydrogenase. Alternatively, the dynamical behavior of proteins can result in intrinsically multiexponential fluorescence anisotropy decays, where the more rapidly relaxing components reflect the amino acid residue segmental motions.$^{[3]}$ Further, many aspects of the changes at the molecular level such as energy transfer,$^{[4]}$ conformational distributions,$^{[5]}$ and transient effects in collisional quenching$^{[6,7]}$ display complex emission kinetics that are accessible from dynamical measurements.

In principle, resolution of the time-dependent decays of anisotropy and/or intensity can be equivalently accomplished using either time- or frequency-domain measurements.$^{[8–16]}$ In the time domain (impulse response approach), the temporal emission from the sample...
following pulsed excitation (ideally a Dirac $\delta$-function) is measured using detectors with high temporal resolution (e.g. streak cameras) or time-sampling circuitry (e.g. time-correlated single photon counting approach). In the frequency domain (harmonic response approach), the emission phase angle lag and modulation attenuation relative to the sinusoidally modulated incident light are measured.

The first analytical paper on time-resolved spectroscopy, published in 1957 by Keirs, Britt, and Wentworth, was based on measuring phosphorescence lifetimes (see O’Connor and Phillips[10]). Some 42 years later, the improvements in optical technology and continued advances in digital electronics and computing power have lead us to the era of ultrafast spectroscopy. Before we discuss these methods that are actually used to measure the anisotropy and/or intensity decay kinetics, it is instructive to look at the general expressions describing fluorescence intensity and anisotropy decay kinetics.

For a system containing $n$ noninteracting fluorescence species (components), following excitation with an optically short Dirac $\delta$-function, the time-dependent emission decay can be described by a multiexponential series of the form, Equation (1):

$$I(t) = \sum_{i=1}^{n} a_i \exp \left( -\frac{t}{\tau_i} \right)$$  \hspace{1cm} (1)

This expression is strictly true for discrete lifetime components. Here, $a_i$ is a pre-exponential factor that represents the fractional contribution of the $i$th component, possessing excited state lifetime $\tau_i$, to the total time-resolved intensity decay. The fractional contribution to the total intensity decay ($f_i$) of each species is then given by Equation (2):

$$f_i = \frac{a_i \tau_i}{\sum_{i=1}^{n} a_i \tau_i}$$  \hspace{1cm} (2)

Of course, nonexponential or complex exponential decays are often observed in what are assumed to be simple systems because of competing processes (e.g. solvent relaxation, energy migration) or inherent heterogeneity. In cases where single or multiple fluorophores are located simultaneously in or interconverting between an ensemble of distinct environments, a distribution of excited state lifetimes reflecting the environmental distributions would be expected a priori. From Equations (1) and (2) it can be shown that:

$$I(t) = \sum_{i=1}^{n} f_i \tau_i^{-1} \exp \left( -\frac{t}{\tau_i} \right)$$  \hspace{1cm} (3)

For the limiting case where the number of emitting centers is large, Equation (3) can be expressed as an integral of the form, Equation (4):

$$I(t) = \int_{0}^{\infty} f(\tau) \tau^{-1} \exp \left( -\frac{t}{\tau} \right) d\tau$$  \hspace{1cm} (4)

Most approaches to the study of excited state lifetime distributions assume that $f(\tau)$ is given by one of several continuous distribution functions, Equations (5–7):

uniform:  \hspace{1cm} f(\tau) = A \text{ from } (\tau - W/2) \text{ to } (\tau + W/2)  \hspace{1cm} (5)

Gaussian:  \hspace{1cm} f(\tau) = A \frac{\exp[-(\tau - \tau')^2/2\sigma^2]}{\sigma\sqrt{2\pi}}  \hspace{1cm} (6)

Lorentzian:  \hspace{1cm} f(\tau) = \frac{A}{1 + [(\tau - \tau')/(W/2)]^2}  \hspace{1cm} (7)

where $\tau'$ is the central or mean lifetime value, $\sigma$ is the standard deviation of the Gaussian distribution, $W$ is the full width at half-maximum (fwhm) for the Lorentzian and uniform distributions, $\tau$ is the lifetime, and $A$ is an amplitude constant determined from the normalization condition, Equation (8):

$$f(\tau) d\tau = 1$$  \hspace{1cm} (8)

In a time-resolved anisotropy decay experiment, the sample is excited with a brief pulse of vertically polarized light and the time dependence of the parallel $[I_{||}(t)]$ and perpendicular $[I_{\perp}(t)]$ components of the fluorescence provide the time-resolved decay of anisotropy $r(t)$, Equation (9):

$$r(t) = \frac{I_{||}(t) - I_{\perp}(t)}{I_{||}(0) + 2I_{\perp}(0)}$$  \hspace{1cm} (9)

For a simple isotropic rotor, $r(t)$ decays with a single rotational reorientation time, $\phi$, Equation (10):

$$r(t) = r_0 \exp \left( -\frac{t}{\phi} \right)$$  \hspace{1cm} (10)

where $r_0$ is the so-called limiting anisotropy measured in the absence of any rotational reorientation. For more complicated systems, $r(t)$ may take the form of a string of exponentials, Equation (11):

$$r(t) = r_0 \sum_{i=1}^{n} \beta_i \exp \left( -\frac{t}{\phi_i} \right)$$  \hspace{1cm} (11)

where $\beta_i$ and $\phi_i$ are the fractional contribution of the total decay of anisotropy and the rotational correlation time
attributed to the \( i \)th apparent rotational reorientation event, respectively.

There are several methods used to obtain excited state intensity decay \( I(t) \) and/or anisotropy decay \( r(t) \). Some of the methods will be discussed here briefly. For a more elaborate description, the reader is directed to the specific literature references provided.

### 1.1 Time Correlated Single Photon Counting

Time correlated single photon counting (TCSPC)\(^{(10–12)}\) relies on the concept that the probability distribution for emission of a single photon after an excitation event yields the actual intensity versus time distribution of all the photons emitted as a result of the excitation. By statistically sampling the single photon emission following a large number of excitation events, the experiment constructs this probability distribution.\(^{(10)}\)

The TCSPC technique was first used by Bollinger and Thomas in 1961 (see O’Connor and Phillips\(^{(10)}\)). To measure the luminescence decay characteristics of scintillators excited by \( \alpha, \beta, \) and \( \gamma \)-radiation. Koechlin (see O’Connor and Phillips\(^{(10)}\)), in the same year, used TCSPC to determine the shapes of scintillator emission curves with resolution in the nanosecond range. By way of illustration, Figure 1(a) shows a TCSPC fluorescence decay curve for a dilute solution of 1-ethylpyrene dissolved in liquid toluene. From the fits and corresponding residuals for single and double exponential decay laws, associated \( \chi^2 \) values and residuals (Figure 1b), it is clear that a double exponential decay law is required to describe the overall decay kinetics adequately.

In TCSPC, as the excited state intensity decay kinetics approach the timescale of the so-called instrument response function (Figure 1a), the discrimination between the two becomes more and more critical to recovering accurate decay constants. The typical way to recover the decay parameters from the decay trace and the instrument response function is to solve the convolution integral, Equation (12):

\[
F(t) = \int_0^t P(t') I(t - t') \, dt'
\]

In this expression, \( P(t') \) is the instrumental response, \( I(t - t') \) is the impulse response from the sample which describes the kinetic model, and \( F(t) \) represents the decay curve. If the measured excited state decay is represented by \( Y(t) \), the goodness of fit (\( \chi^2 \)) between \( F(t) \) and \( Y(t) \) can be optimized by iterating the parameters in \( I(t) \) via assessing using normalized chi-squared values (\( \chi^2 \)) where, Equation (13):

\[
\chi^2 = \frac{1}{N-n} \sum_{i=1}^{N} \frac{(Y_i - F_i)^2}{Y_i}
\]

for \( N \) data points and \( n \) fitting parameters. For a good fit, \( \chi^2 \) should be “close to unity” (see Figure 1).\(^{(10)}\)

### 1.2 Multifrequency Phase and Modulation Fluorometry

In the frequency domain, the sample under study is excited with sinusoidally, amplitude-modulated light.\(^{(13–15)}\) Typically, these frequencies span the megahertz to gigahertz regions and have been generated by using acousto-optical, electro-optical or piezo-optical devices, continuous wave (CW) or mode-locked lasers, and synchrotron sources.\(^{(13)}\) The resulting time-dependent fluorescence is slave to the frequency of the excitation waveform, but is phase shifted (\( \theta \)) and amplitude demodulated (\( M \)) to an extent dependent on the fluorescence lifetime(s) inherent to the sample. For any
decay process the calculated (denoted by subscript c) values of θ and M are given by Equations (14) and (15):

\[ \theta_c(w) = \tan^{-1} \frac{S(w)}{C(w)} \] \hspace{1cm} (14)

\[ M_c(w) = \left( [S(w)]^2 + [C(w)]^2 \right)^{1/2} \] \hspace{1cm} (15)

where \( w \) is the angular frequency and, for a single exponential decay, Equations (16) and (17):

\[ \frac{S(w)}{C(w)} = \frac{v}{w} \] \hspace{1cm} (16)

and

\[ [S(w)]^2 + [C(w)]^2 = \left( 1 + w^2 \tau^2 \right)^{-1} \] \hspace{1cm} (17)

For a general decay model expressed by Equation (1), the frequency-dependent sine \( S(w) \) and cosine \( C(w) \) Fourier transforms are given by Equations (18) and (19):

\[ S(w) = \int_{0}^{\infty} I(t) \sin wt \, dt \] \hspace{1cm} (18)

\[ C(w) = \int_{0}^{\infty} I(t) \cos wt \, dt \] \hspace{1cm} (19)

The decay times are recovered by experimentally measuring \( \theta_m(w) \), the frequency-dependent phase shift, and \( M_m(w) \), the frequency-dependent modulation, values while probing the sample at several angular modulation frequencies (\( w = 2\pi f \), where \( f \) is the linear modulation frequency in hertz), followed by analysis using nonlinear least squares fitting algorithms. In this approach, the sum of the squared differences between the calculated (\( \theta_c(w) \) and \( M_c(w) \)) and measured (\( \theta_m(w) \) and \( M_m(w) \)) values are minimized using the \( \chi^2 \) as a measure of the goodness-of-fit, Equation (20):

\[ \chi^2 = \frac{1}{D} \sum_{w} \frac{(\theta_m(w) - \theta_c(w))^2}{v^2_\theta} + \frac{1}{D} \sum_{w} \frac{(M_m(w) - M_c(w))^2}{v^2_M} \] \hspace{1cm} (20)

Here, \( v_\theta \) and \( v_M \) are the variances in the measured phase angle and demodulation, respectively, and \( D \) is the number of degrees of freedom. When \( v_\theta \) and \( v_M \) reflect accurately the uncertainties in the \( \theta \) (phase angle) and \( M \) (demodulation) experimental measurements, the fit quality is judged by the closeness of \( \chi^2 \) to unity, the randomness of the phase angle and demodulation residuals about zero, and the physical significance of the model. Figure 2 shows a typical phase-modulation data set for calcium green dissolved in pH 7.2 phosphate saline buffer (10 mM in Ca(II)). In Figure 2(a), the points denote the experimental data and the fit to a single and double exponential decay law are shown. The fit of these data to a double exponential decay law is far superior to the fit to a single exponential decay law. Frequency-dependent phase and demodulation residuals (Figures 2b and 2c) demonstrate the difference between the fit to a single and double exponential decay law.
1.3 Pump–Probe Spectroscopy

For measurement of very fast relaxation processes which demand a time resolution below $10^{-10}$ s, most detectors are simply not fast enough (with the notable exception of streak cameras which, besides being very expensive, are restricted in their application by lower sensitivity, lower dynamic range, and the necessity of careful calibration and alignment). In this case, the pump–probe technique offers the best alternative. In this technique, the species under investigation are excited by a fast laser pulse (i.e. pump) (Figure 3a). A second laser pulse, with a variable delay time $\Delta t$ relative to the pump pulse, probes the time evolution of the excited state population density (Figure 3b). The signal intensity is proportional to the fluorescence intensity, provided that the probe pulse is not overly intense. The probe pulse arrival time is controlled by physically changing the probe beam optical path (Figure 3c). Incremental variation in the arrival time (i.e. probe pulse delay) allows the temporal decay function to be constructed.

In pump–probe spectroscopy, the time resolution is limited by the fundamental laser pulse widths and not by the detector intrinsic response time. The ability to generate ultrafast laser pulses thus allows pump–probe spectroscopy to be performed on a subpicosecond scale.

Figure 3 (a) In pump–probe spectroscopy, molecules under investigation are excited by a fast laser pulse on the $|0\rangle \rightarrow |1\rangle$ transition. (b) A probe pulse with a variable time delay $\Delta t$ against the pump pulse probes the time evolution of the population density $N_i(t)$. (c) Schematic of a simplified instrumental set-up used in pump–probe spectroscopy for the measurement of an ultrafast relaxation processes. (Adapted from Demtroder.)
timescale. Moreover, a broader range of applications is opened up by using two independently tunable ultrafast lasers that use the same pump laser to synchronize the pump and probe pulses.

1.4 Up-conversion

Another method that is well suited for the determination of excited state fluorescence anisotropy and intensity decay kinetics is termed up-conversion. This methodology subpicosecond fluorescence anisotropy and intensity decays to be determined.\(^{16}\) Up-conversion refers to the nonlinear phenomenon of sum-frequency generation within anisotropic crystals. Figure 4 shows a general schematic of an up-conversion instrument. This method relies upon the generation of a signal of frequency \(\omega_3\), which is the sum frequency for fluorescence \(\omega_2\) and the exciting laser frequency \(\omega_1\). In this case, \(\omega_3\) can be distinguished spatially as well as by its frequency. When used to measure fluorescence decays, up-conversion offers several advantages over TCSPC. As well as vastly improved time resolution, it permits detection of fluorescence in the far red and infrared without the use of red-sensitive detectors. For example, fluorescence at 900 nm can be mixed with laser light at 600 nm to generate a sum frequency at 360 nm. The primary disadvantage, however, is that up-conversion of fluorescence toward the blue end of the spectrum is more difficult owing to the absence of efficient mixing crystals operating in the far ultraviolet. The ultimate time resolution of an up-conversion experiment is set by the excitation pulse duration.

2 INSTRUMENTATION

Since the early 1980s, significant advances have been made in instrumentation for time domain and frequency domain fluorescence spectroscopy. With present time domain instrumentation and optical up-shifting techniques, femtosecond processes are now being routinely explored.

2.1 Time Domain\(^{10,12}\)

The additional specialized equipment needed to implement TCSPC includes a pulsed light source such as a laser or spark discharge, a fast response detector, and a time-to-amplitude convertor (TAC). Figure 5 shows a simplified schematic of a TCSPC instrument. It is important to mention here that several additional instrumental refinements are required but are of secondary importance and beyond the scope of this article. The reader is directed to O’Connor and Phillips\(^{10}\) for a more detailed discussion. The TAC, the most critical device in the time correlation process, measures the elapsed time between the initial rise in intensity of the pulsed light source and the detection of an emitted photon.\(^{12}\) In operation, an electrical pulse is generated at a time exactly correlated with the time of generation of the optical pulse by the trigger (e.g. a PMT output, an antenna pick-up, or a logical synchronized pulse). After receiving the trigger pulse, the TAC initiates the charging of a capacitor plate which is routed to the TAC start input via a discriminator. While the same optical pulse that triggered the TAC excites the fluorescent sample, an aperture is adjusted on the emission arm so that only one photon is detected for every 100–200 excitation events. The signal resulting from this photon stops the charging ramp in the TAC, which transmits a pulse. The amplitude of this pulse is proportional to the charge in the capacitor, and hence to the time difference between the start and stop pulses. The TAC output pulse is given a numerical value within the analog-to-digital converter (ADC) and a count is stored in the data storage device (a multichannel pulse height analyzer; MCPHA) in an address corresponding to...
Figure 5 Simplified block diagram of a conventional TCSPC apparatus (Adapted from O’Connor and Phillips\(^{10}\) and Cline-Love and Shaver\(^{12}\)). Please refer to the text for further experimental description. MCA/PC, Multichannel Analyzer Personal Computer.

that number. Excitation and data storage are repeated in this way until the histogram of number of counts against address number in the storage device represents, to some required precision, the decay curve of the sample\(^{10}\). A typical TCSPC trace from a flash lamp-based instrument is illustrated in Figure 1. With current pulsed laser sources and microchannel plate PMT detectors, it is possible to determine excited state processes routinely on the low picosecond timescale.

2.2 Frequency Domain

In the frequency domain\(^{13}\), the latest instrumentation has made it possible to measure picosecond decay kinetics routinely. These advances have been made possible by the use of excitation sources with large bandwidths and detectors with high gain and wide bandwidths\(^{13}\).

A simplified schematic for a multifrequency, cross-correlation\(^{14}\) phase and modulation instrument that is capable of parallel acquisition of phase and modulation data is presented in Figure 6. In a frequency domain measurement, the excitation source can be an intensity modulated CW light source or a high repetition rate pulsed laser. The choice of source usually depends on the required wavelengths, the power level needed, and the experience and other constraints of the researchers. Laser sources can be easily modulated using one of several modulation schemes\(^{13}\). In most modern frequency domain instruments, the harmonic content of pulsed lasers produces modulation to many gigahertz such that the bandwidth of frequency domain instruments is now limited only by the detector response time\(^{14}\).

To illustrate the range of light sources used in phase modulation fluorescence, we have selected two extreme examples. Sipior et al.\(^{18}\) demonstrated the use of an inexpensive, commercially available blue light emitting diode (LED) to produce amplitude-modulated near-ultraviolet light as a source for nanosecond phase-modulation fluorescence lifetime measurements. The most recent advance in multifrequency phase and modulation fluorescence has been the development of instrumentation for the parallel acquisition of phase and modulation data\(^{19–21}\). In this design, the phase and modulation across the entire

Figure 6 Simplified schematic of a multiharmonic Fourier phase and modulation fluorometer. The dashed lines denote optical paths while the solid lines indicate electrical connections. Abbreviations represent power amplifiers (A1, A2); PMT detectors (PMT1, PMT2); and harmonic comb generators (HCG1, HCG2). (Adapted from Bright et al.)\(^{13}\)
frequency spectrum can be collected simultaneously and experiments that took about 1 h can now be completed in <10 s. More recently, a parallel multiharmonic frequency domain fluorometer was designed by Bright et al. that can rapidly measure excited state fluorescence anisotropy and intensity decay kinetics following one-, two-, or three-photon excitation.

3 SOLVATION DYNAMICS

The time evolution of an emission spectrum provides insight into how the local solvent environment affects the emission process. Time-resolved fluorescence experiments have been used to study the energetics of the solvation process, because fluorophores provide an internal clock from which to observe processes occurring on the fluorescence timescale. That is, if a secondary process (a reaction) occurs on the same timescale as fluorescence, it can often perturb the fluorescence intensity decay kinetics. Thus, the kinetics of the secondary process can be inferred via its impact on the time-resolved fluorescence decay. Bakshiev, Mazurenko, and co-workers pioneered the use of time-resolved fluorescence for transient solvation studies (see Ravichandran and Bagchi, Simon, Nagarajan et al.). Initial experiments in this field were limited by the nanosecond time resolution of early instrumentation. As a consequence, the majority of these experiments were carried out in viscous solvents, at relatively low temperatures, and/or on samples dissolved in nonpolar (noninteracting) solvents modified (perturbed) by the addition of small amounts (<1% by volume) of a polar cosolvent. In this way, these investigators were able to bring the solvation process “down to” the time regime of their instrumentation. Recent advances in instrumentation have now made it possible to perform studies in neat liquid solvents like acetonitrile, water, methanol, and other alcohols. Subpicosecond spectroscopy has also been used by to study the microscopic solvation dynamics of less viscous liquids.

In order to understand the time evolution of spectral shifts due to universal excited solute–solvent interactions, it is useful to invoke the Franck–Condon principle. Upon excitation, a molecule will retain the particular solvent configuration which is favored in the ground state, because solvent molecules cannot reorient during the excitation event. If the excited state, formed directly by light absorption or indirectly via a fast subnanosecond reaction, has a new dipole moment, and if the solvent relaxation time is less than the excited state fluorescence lifetime, the solvent dielectric medium surrounding the fluorophore will be polarized differently from in the ground state. Thus, a new reaction field developed by this orientation strain is created by the fluorophore and the solvent molecules surrounding this new dipole will relax and reorient to accommodate the change in dipole moment of the excited fluorophore until equilibrium has been restored. When this solvent relaxation time becomes comparable to the excited state fluorescence lifetime, time-resolved spectral shifts in addition to electronic relaxation will be observable.

Pierce and Boxer reported the time-dependent solvation for a fluorophore within a protein by following the time-dependent fluorescence Stokes shift. Specifically, these authors reported on the complex formed between sperm whale apomyoglobin and 2′-(N,N-dimethylamino)-6-naphthoyl-4-trans-cyclohexanoic acid at temperatures between 243 and 298 K. The decay of the mean emission energy was not single exponential and there were decay components spanning and probably exceeding their experimentally observable time window (20 ps to 20 ns). These results suggested that either the activation energies of the rate-limiting motions in the relaxation are dependent on substrate conformation, or that different types of protein motion with different characteristic frequencies participate in the relaxation.

Mertz et al., while investigating how the Stokes shift of proflavin was affected by solvent dipolarity, reported that the dependence of the solvent reorganization free energy on the solvent dielectric properties can be explained if two effects are taken into account. The first effect is the distortion of dielectric properties of a uniform solvent by embedding a bulk solute molecule in the solvent. The second effect is the influence of the solvent dipolarity on the electronic density redistribution upon an electronic transition event. These particular data also supported the notion that the commonly adapted equation for Stokes shift that establishes equality between Stokes shift and the doubled reorganization energy is not rigorously true, in general. Indeed, these authors showed that the measured experimental data are consistent with a more rigorous and appropriate approximation of Stokes shift that takes into account the quantum nature of the solute local modes.

Rempel et al., using temperature-dependent time-resolved Stokes shift measurements of Coumarin 153 (C153), explored the solvation dynamics in binary mixtures of alcohols and alkanes and concluded that, depending upon the actual alcohol concentration, the Stokes shift takes place on a timescale ranging from 300 ps to several nanoseconds. These characteristic times were two orders of magnitude longer than the relaxation times typically observed for C153 dissolved in neat alcohols. This effect was attributed to solvent/cosolvent rotational reorientation. These authors also observed that the temporal behavior of the Stokes shift was monoexponential and the time constants depended
linearly on the alkane viscosity. They concluded that their data strongly support a diffusion-controlled process of solvation in these mixtures.

Glasbeek et al. used fluorescence up-conversion of 1-phenyl-4-[4-cyano-1-naphthyl]methylene]piperidine (PCNMP) in its lowest excited charge transfer state when dissolved in a series of solvents. These experiments were performed at room temperature with 300 fs time resolution. The observed Stokes shift was attributed to the solvent response to the large photoinduced PCNMP dipole moment (~30 D). The solvation dynamics were reported to be governed by the rotational diffusional motions of the ethereal solvent molecules.

Solvent relaxation of indole dissolved in polar protic solvents and analysis of the fluorescence lifetime distributions and time-dependent spectral shifts were reported by Demchenko et al. These authors used the maximum entropy method (MEM) and obtained relatively narrow peaks for the fluorescence lifetime distribution, which originate first from the main emission decay component and second from additional short components which are due to spectral kinetic processes. These short-lived components were extremely sensitive to temperature. The authors were also able to use time-resolved emission spectroscopy to reveal relaxation times over the same range recovered for the observed lifetime distributions. Results of excited state stabilization energy measurements, combined with time-dependent spectral shifts, were found to be consistent with a mechanism of general dielectric solvent relaxation rather than formation of binary excited state complexes in the time range studied.

Wendt and Richert recently reported the Stokes shift and Stokes shift dynamics for naphthalene (change in dipole moment upon excitation ~0 D) and quinoxaline (~1.3 D) dissolved in n-propanol and other glass-forming solvents. The time dependence of the Stokes shift for naphthalene was reported governed by the structural (or shear stress) relaxation time of n-propanol, without any signature from the strong dielectric relaxation. For this solvent, structural and dipolar contributions can be distinguished because the timescale for dipolar reorientation is 25-fold slower than the shear stress relaxation time. These authors concluded that the naphthalene solvation reflects excitation-induced changes in the van der Waals interactions, which makes it an ideal probe for assessing shear stress or mechanical relaxations on microscopic spatial scales near the glass transition temperature ($T_g$).

In a recent review, Fleming and Cho present experimental and theoretical studies of polar solvation dynamics and spectral line broadening. Spectral broadening, arising from interactions with the environment in the time domain (the dephasing timescale), is an effect arising from the averaging over the ensemble that is intrinsic to linear spectroscopic measurements. An important feature of time-resolved fluorescence and ultrafast spectroscopy is that they can be used to undo the ensemble average and allow molecular dynamics to be observed directly in condensed phases.

Bright et al., during their investigation of the behavior of acrylodan-labeled bovine serum albumin and acrylodan-labeled human serum albumins (BSA-Ac and HSA-Acs) sequestered within a tetramethylorthosilane-derived xerogel, used the dipolar relaxation kinetics to quantify the relaxation of the Ac fluorophore cybotactic region following optical excitation. These results suggested that there was a substantial amount of nanosecond and subnanosecond dipolar relaxation within the local environment surrounding cysteine-34 in both proteins, even when they were sequestered within “dry” xerogels. The solvation dynamics of BSA-Ac and HSA-Ac differ with the initial xerogel preparation, suggesting that the slight differences in amino acid sequences do indeed affect the cybotactic region surrounding the Ac residues within these proteins.

4 APPLICATIONS IN BIOCHEMISTRY AND BIOPHYSICS

Time-resolved fluorimetry is probably second only to NMR (nuclear magnetic resonance) in its ability to solve diverse and significant problems in the biochemical and biophysical sciences. In particular, stems from signal inadequacy, sample scarcity or special constraints, fluorescence spectroscopy is uniquely suited to tackle such problems. Areas of recent study include immunoassay, enzymatics, protein–ligand binding, biosensor development and diagnostics, denaturation kinetics, nucleic acid determination, oligonucleotide hybridization, and protein self-association.

Time-resolved fluorescence is an invaluable tool for studying processes involving primary energy and charge transfer in photosynthesis and photosensitization. For example, our understanding of photosynthesis was largely achieved by performing dynamic fluorescence experiments over several timescales. As a result of such efforts, a contemporary view of photosynthetic kinetics has been realized. Although many aspects of the process are still veiled in mystery, the most widely accepted model of the photosynthetic membrane includes four features essential to the complex electron-transfer mechanisms: (1) photosystem I (PS I) and II (PS II) reaction centers which operate in series to effect charge separation, (2) a pigment-binding protein light-harvesting assembly, (3) a membrane to isolate products physically, and (4) requisite redox and assembly enzymes.
In photosynthetic pathways, appropriately energetic trapped photons promote electrons into higher energy excited states. Electrons in these elevated states, however, tend to decay to ground singlet states on a nanosecond timescale, wasting potential energy in the form of light and heat. In order to prevent this scenario, chromophores must donate excited electrons to quinone acceptors faster than the rate of excited state decay (i.e. recombination). The resulting charge separation at the reaction center chemically preserves some of the incident photon energy in the form of a stable transmembrane electrical potential.

The role of protein–chromophore interactions in the mechanism of energy transfer was probed by de Paula et al.\textsuperscript{(35)} by using time-resolved fluorescence to study chlorophyll a bound to the 47 kDa antenna protein (CP47) of spinach PS II. These authors used picosecond fluorescence spectroscopy to characterize CP47 and distinguish between functional (intact or perturbed) and nonfunctional (denatured) centers in various formulations. The structural heterogeneity (e.g. donor–acceptor distance, vibronic coupling) gives rise to multiple recombination rates which are manifest in the multieponential decays observed.

The field of photosensitization is another expanding area of application for dynamic fluorimetry. For example, photodynamic therapy (PDT) involves the administration and photoactivation of a suitable photosensitizing agent as a medical means of treating solid, localized tumors.\textsuperscript{(33,36)} In PDT, it is generally accepted that energy transfer takes place from a luminophore excited triplet state to ground state triplet oxygen to produce the cytotoxic singlet oxygen. Although numerous dyes such as the acridines, coumarins, and porphyrins have been studied for their tumor-localizing properties and effectiveness as potential PDT agents, research has increasingly centered on hematoporphyrin derivatives and Photofrin II\textsuperscript{®} (a proprietary drug marketed by Quadra Logic Technologies Inc.). Unfortunately, Photofrin II\textsuperscript{®} has been found to be a complex mixture of monomers, “dimers” (dihematoporphyrins formed by ether or ester linkages), and aggregates. Further, the most tumor-localized components are not necessarily the best photosensitizers making pharmacokinetic assessments difficult. Time-resolved fluorescence has been used to differentiate between these various components providing useful information about the uptake, retention, and aggregation dynamics of the drug forms in tumors and tumor-free tissues. In addition, new or unexplored molecules can be characterized as potential lead compounds for PDT based in part on their excited state luminescence lifetimes. Chlorin and bacteriochlorins are currently being investigated by Pandey and others because these agents exhibit high absorbances at higher wavelengths allowing them to be more effectively photoexcited when they are loaded more deeply into cancerous tissue making the treatment of large deep-seated tumors more effective.\textsuperscript{(33,36)}

Our understanding of the complexity of genomes in various cell types has grown considerably with the development of recombinant DNA techniques and sensitive methods for analyzing the organization of specific genes. Such techniques rely on specific nucleic acid hybridization probes which have become irreplaceable in contemporary molecular biology for the detection of specific, complementary nucleic acid sequences. However, stability, detection sensitivity, safety, and disposal problems common to use of radioisotopes (\textsuperscript{32}P, \textsuperscript{3}H, \textsuperscript{13}C) have stimulated interest in nonisotopic alternative labels. The high specific activity and simplicity associated with the use of luminescent probes (e.g. acridine), when measured by time-resolved fluorometry, provide powerful nonradioactive substitutes in the field of nucleic acid hybridization. Popular among these alternatives, lanthanide labels covalently bound to nucleic acids have shown unique promise in areas of diagnostic medicine. To date, there have been applications in areas like genetic predisposition to disease including inherited disease, viral infection, bacterial identification, and antibiotic sensitivity testing.\textsuperscript{(33,34)}

A novel technique for screening point mutations was developed for diagnosis of familial defective apolipoprotein B-100 (FDB) by coupling polymerase chain reaction (PCR) performed on the appropriate region of the apoB gene with time-resolved fluorometric detection.\textsuperscript{(37)} Like its cousin familial hypercholesterolemia (FH), FDB affects the interaction between cellular low density lipoprotein receptors and the proper ligands on plasma lipoproteins apoB-100 and apoE. However, unlike FH where a large number of various mutations occur, FDB involves a single point mutation corresponding to amino acid position 3500. In practice, the PCR amplification products are hybridized in situ with Eu\textsuperscript{3+}-labeled oligonucleotides complementary to either the wild type or the mutant genome. This allows the presence or absence of the apoB-100 mutation to be monitored based on the europium chelate excited state lifetimes. When a sample population of 127 Swedish patients clinically diagnosed with heterozygous FH were screened by this method, two were correctly identified as actually suffering from FDB.

By following a similar strategy, a method for simultaneous multicolor analysis of PCR products for any of seven amplified human papilloma virus (HPV) types was reported.\textsuperscript{(38)} HPV infection has been associated with multiple cancer types (primarily anogenital) and identification is, as such, important to determine the risk of cervical carcinoma in women. In this approach, the authors perform a seminested PCR in a single tube using a biotinylated inner primer. Amplification products were captured on streptavidin-functionalized 96-pronged manifold solid supports, and then denatured to render...
single-stranded molecules serving as targets in subsequent hybridization reactions. These targets were then probed with a mix of seven type-specific (HPV types 16, 18, 31, 33, 35, 39, and 45 associated with cervical cancer), differentially labeled nucleotides containing 10 or 20 lanthanide chelates at the 5’ ends with seven distinct combinations of Eu$^{3+}$, Tb$^{3+}$, and Sm$^{3+}$ ions. After a washing step in microtiter wells, the lanthanide ions were released from the bound probes. This allowed the seven viral strains to be correctly identified by time-resolved fluorescence measurements.

Proteins are dynamic in nature and their function and behavior are intimately related to their structure, conformation, and dynamics. Thus, if one aims to understand and exploit events that rely on protein conformational changes (e.g., protein–drug/ligand association, antigen/hapten–antibody binding, enzyme–substrate interactions, protein–membrane insertion, protein self-association), it becomes necessary to track, quantify, and ultimately understand the behavioral aspects of proteins as they undergo net conformational changes (measurements at or near equilibrium) and particularly as conformations change in near real time. Advances in protein physical chemistry have been made as a result of combining novel fluorescent probes and coupling chemistries with the information rich nanosecond and subnanosecond time-resolved optical techniques. In contrast to techniques like NMR and X-ray crystallography, subnanomolar protein concentrations can routinely be studied by fluorescence allowing assessment of association parameters under true equilibrium conditions. Recent results by Ingersoll et al.\textsuperscript{(39)} illustrate the potential of on-the-fly phase-modulation fluorescence to track the nanosecond and subnanosecond dynamics of BSA-Ac. In these experiments, the authors determined the temporal evolution of fluorescence anisotropy and intensity decay kinetics of BSA-Ac when it was challenged with trypsin or β-mercaptoethanol (BME) (Figure 7). Both the BME-induced disulfide interchange and the trypsin-mediated protein digestion were successfully tracked on-the-fly by multiharmonic Fourier fluorescence suggesting the potential of dynamic optical techniques for real time reaction monitoring.

Molecular behavior at interfaces is of critical importance in areas ranging from energy conversion, chromatography, and catalysis to toxicity, adhesion and transport properties, and chemical sensing. By using time-resolved fluorescence in concert with interfacially selective detection (generally by exploiting some total internal reflection configuration), the underlying kinetics and mechanisms associated with surface bound molecules can be accessed even in aqueous media.\textsuperscript{(40)} Such information is relevant to the study of biosensor interfacial dynamics where the ultimate performance is governed by the complex interplay among the biorecognition element (BRE) structure and the conformation at the interface, the ease with which the target analyte can reach and interact with the BRE, and the homogeneity, stability, and mobility of the BRE at the interface. In this context, the Bright group developed multifrequency phase modulation total internal reflection fluorescence (MPM/TIRF) to study in situ the interfacial distribution of surface immobilized BRE dynamics.\textsuperscript{(41)} Initial work showed that an immunosurface composed of F(ab’)$^\text{2}$ antifluorescein polyclonal antibodies at a fused silica surface on interacting with free fluorescein hapten consisted of a broad distribution of microdomains. In contrast, the F(ab’)$^\text{2}$–fluorescein system in solution was described by a single discrete microdomain (i.e. excited state fluorescence lifetime).
That is, an ensemble of F(ab\(^\rightarrow\)) fragments having slightly different binding site occupancies, surface-induced conformational changes, and/or actual affinity constants exists at and is modulated by the surface. Also, these species change/drift with storage time causing loss of immunosurface integrity over time.

A powerful hybrid technique called phase-resolved evanescent wave induced fluorescence (PREWIF) was reported by Lundgren et al. (42) for studying interfaces by combining the interfacial selectivity inherent to TIRF (total internal reflection fluorescence) with the temporal and spectral resolution of phase-resolved fluorescence. The potential of PREWIF for in situ studies of heterogenous interfaces under ambient conditions was demonstrated by resolving individual components of heterogenous interfaces under ambient conditions. These researchers were also able to resolve the static emission from an ~100 Å thick immunosurface composed of protein G-antifluorescein-bound fluorescein even in the presence of excess free fluorescein in the bulk. PREWIF was also used to recover the relaxed and unrelaxed spectra contributing to the overall fluorescence from BSA-Ac physisorbed onto a quartz surface.

5 POLYMER PHOTOPHYSICS

Processes involved in polymer chain dynamics span a wide range of time and lengthscales. The large scale motions of polymer chains have historically been analyzed in terms of normal modes where higher order modes correspond to motions on faster timescales and on shorter lengthscales. Polymer chain dynamics on sufficiently short lengthscales depend greatly on the chemical structure of the polymer chain itself. (43–50) Polymer photophysics, both in its historical development as well as its current practice, can be divided into a few regimes of study: excimer formation, fluorescence anisotropy, fluorescence quenching, and excited state energy migration. Time-resolved optical spectroscopy provides a uniquely detailed picture of local segmental motion during polymer chain dynamics. (43)

This is accomplished by observing the time dependence of the polymer orientation autocorrelation function directly. A common feature of time-resolved fluorescence methods is the use of nonfluorescent polymer chains with an extrinsic chromophore label attached. Alternatively, the emission from an intrinsic polymer-bound fluorophore can be used to investigate the energy migration as well as polymer. (43, 44)

A typical time-resolved fluorescence experiment measures the rotational reorientation of a fluorophore. If the said fluorophore is part of a polymer chain or in registry with the chain, then polymer chain motions can be inferred by observing the chromophore rotational reorientation. The detection limits of fluorescence allow such measurements to be made even at a level of one chromophore per 1000 oligomeric repeat units (i.e. a chain concentration of 0.1%). When a chromophore with a strongly polarized electronic transition is excited by polarized light, those chromophores with absorbance transition moments aligned in the direction of the excitation polarization are preferentially excited. If these chromophores emit before they significantly reorient or depolarize, the fluorescence will also be preferentially polarized (i.e. anisotropic) along this direction. The fluorescence polarization depends upon the interrelation of two physical parameters: the excited state fluorescence lifetime and the molecular rotational reorientation time. (44)

Most of the work using time-resolved fluorescence to investigate local polymer dynamics has been performed using dilute solutions of fluorescently labeled polymers. (44) These studies provide an opportunity to understand local chain motions without considering the complicating effects of chain–chain interactions present in more concentrated systems. It is important to mention here that the timescales for local dynamics in solution are comparable to the fluorescence timescale. Recently, a charge transfer fluorescence molecule was used as a probe to study the structure of polystyrene lattices and polystyrene–glycidylmethacrylate core–shell latices. (45) Information on the composition of the latex was obtained by using steady-state and time-resolved fluorescence measurements. The fluorescent probe, PCNMP, that was used in these studies has a dipolar excited state which is populated by excitation in the ultraviolet range by an intramolecular electron transfer process. As is typical for charge transfer luminescence, however, the emission spectra are rather broad, limiting static fluorescence to qualitative observations because the broad emission spectra make it difficult to distinguish between several coinciding species. By using excited state intensity decay information as an additional experimental observable, Hofstraat et al. (45) were able to provide a clearer picture of such a complicated system.

In another study, time-resolved fluorescence spectra of poly(N-vinylcarbazole) in solution were analyzed by using a principal multivariate spectral estimation method. (46) The data clearly indicated that the polymer emission spectra were composed of precisely three emitting species (monomer, partial overlap excimer, and sandwich excimer). Intensity rise as well as decay curves of the fluorescence of each component are complex and depend on the polymer tacticity. These authors determined that the partial overlap excimer was formed not only by ultrafast trapping in the pre-existing site.
but also through dynamic processes such as energy migration. It was further reported that the excited state monomer and the partial overlap excimer were produced via sandwich excimer dissociation and reactivation. In organized molecular systems, structural inhomogeneity, giving rise to various excited state species is ubiquitous, suggests the broad applicability of such an approach.

Time-resolved fluorescence anisotropy measurements are particularly attractive because they allow work to take place under dilute conditions and they provide an intrinsic molecular ruler (i.e. the dimensions of the fluorophore). Time-resolved fluorescence anisotropy techniques have been used to investigate fluorophore–polymer interactions in the bulk, to follow subunit dynamics, and to track the motion of the elastic cross-link junctions within various polymers. According to Soutar et al., in studies of macromolecular dynamics, emission anisotropy measurements are the most informative of the luminescence-based approaches that can be adopted. Fluorophores simply dispersed in the medium of interest can furnish information on the local free volume accessible to the probe whereas covalently bound fluorophores can reveal details regarding the kinetic behavior of chain segments, termini, and substituent groups. Bolstering their claims, Soutar et al. reported on the intramolecular segmental relaxation behavior of poly(methyl methacrylate) (PMMA) and poly(methyl acrylate) (PMA) at low concentration dissolved in dichloromethane by using time-resolved fluorescence anisotropy. The fluorescence anisotropy decay kinetics of each polymer, over the temperature range of 230–310 K, were adequately described by single exponential models for acenaphthylene- and 1-vinylanthelene-based labels. The recovered rotational reorientation times for segmental motion exhibited an Arrhenius dependence in the temperature range studied, giving rise to activation energies of 14 and 11 kJ mol$^{-1}$ for PMMA and PMA, respectively. These values are considerably lower than those reported for either polymer in other common solvents. In fact, the magnitude of the differences in activation energies are too large to be explained on the assumption that the solvents function solely to provide frictional resistance to the polymer dynamics. These authors suggested that: (1) PMMA and PMA exhibit specific interactions with dichloromethylene and/or other solvents, such as toluene or (2) the naphthyl labels may actually experience specific interactions with dichloromethane which distort the apparent polymer behavior.

Stein, Hoffman, Frank, and Fayer have used time-resolved fluorescence anisotropy decays to investigate the reorientational dynamics of a cross-link junction in poly(dimethylsiloxane) networks from a chromophore attached to the cross-link between $T_g + 75$ K to $T_g + 150$ K. At the junction, the probe chromophore, 1-dimethylamino-5-sulfonylnaphthalene amide (dansyl amide), lies pendant to a silicon that acts as a trifunctional cross-linking atom. In cyclohexanol, the fluorescence anisotropy decays for the chromophore are in agreement with the Debye–Stokes–Einstein hydrodynamic theory of rotational diffusion, demonstrating that the cross-linker can be used as a probe of reorientational relaxation. The fluorescence anisotropy decay kinetics are remarkably fast for a cross-linked poly(dimethylsiloxane) network, reflecting fast rotational reorientation of the cross-link junction. This reorientation appears diffusive and has a temperature dependence in accord with the Williams–Landel–Ferry equation. A model was proposed suggesting that reorientational and translational motion of the cross-link occur simultaneously and both are coupled to fluctuations of the polymer chain termini.

Niemeyer and Bright used time-resolved fluorescence anisotropy and reported on the effects of polymer molecular weight, temperature, and near- and supercritical CO$_2$ gas sorption on the rotational reorientation dynamics of a model solute, $N,N'$-bis-(2,5-di-tert-butylphenyl)-3,4,9,10-pyrenedicarboximide (BTBP), dissolved in poly(dimethylsiloxane). These authors showed that there is a linear correlation between the BTBP rotational reorientation time and the poly(dimethylsiloxane) polymer bulk density. Temperature-dependent studies of the BTBP/poly(dimethylsiloxane) system showed that the BTBP rotational reorientation dynamics are accurately described by an Arrhenius activation model where the recovered activation energies for the BTBP rotational reorientation are statistically equivalent to those for poly(dimethylsiloxane) viscous flow. The addition of CO$_2$ to the BTBP/poly(dimethylsiloxane) system led to appreciably decreased BTBP rotational reorientation times with increased CO$_2$ pressure. These results illustrate how polymer dilation by CO$_2$ can be used to tailor the dynamics within polymer systems.

6 APPLICATIONS IN THE SEPARATION SCIENCES

Because the chromatographic retention time and excited state fluorescence lifetime of a solute are independent phenomena, they contain orthogonal information about the identity of a particular analyte. Time-resolved fluorescence techniques have been applied to reverse-phase HPLC (high-performance liquid chromatography), capillary electrophoresis (CE) and other separation techniques. Loss in selectivity due to overlapping peaks is a major problem encountered in the detection process based on retention times alone. Further, detection at only one or a
few emission/excitation wavelengths may be inadequate to resolve overlapping “chromatographic” peaks, while the use of an array detector to collect an entire spectrum can decrease sensitivity as a result of dispersion. Thus, if selectivity is not substantial, it may be impossible to detect the presence of minor components or matrix effects. Lytle et al. pioneered using time-resolved fluorescence to identify and resolve overlapping chromatographic peaks as well as to indicate the presence of impurities and matrix effects. In the Lytle method, the eluent excited state fluorescence lifetime is determined on-the-fly during liquid chromatographic separation. The lifetimes provided the additional selectivity needed to confirm peak assignments based on retention time. Lytle and his associates emphasized that a combination of coarse excited state fluorescence lifetime measurement and retention time yielded more information about the identity of an unknown than extremely refined measurement of either one alone. The Lytle measurements were made in the time domain by using a pulsed laser for excitation and a PMT detector. The PMT anode current was split in half and one portion was delayed by 10 ns before being sent to one input of a two-channel oscilloscope. Two intensity chromatograms were thus obtained representing two different delay times separated by 10 ns. A ratio of the two chromatograms provided a ratiogram in which each lifetime was identified by a unique concentration-independent ratio, whereby a changing ratio across a peak was indicative of coelution. Results of experiments with polycyclic aromatic hydrocarbon (PAH) standards of known identity were used to illustrate the methodology. Further, 15 PAHs were positively identified in combustion products, illustrating the applicability of these lifetime chromatography measurements to real samples.

Frequency domain fluorescence has been used to detect and resolve overlapping peaks on-the-fly in reverse-phase HPLC. Direct, simultaneous measurements of fluorescence intensity, phase-shift, and demodulation were made at 1 s time intervals for PAHs as they eluted from the chromatograph. During early investigations, these experiments were hindered by limitations of the frequency domain spectrofluorometers, which could only collect data at one modulation frequency per chromatogram thereby necessitating multiple sample injections. The resulting chromatograms had to be perfectly overlaid and the data combined at each point along the chromatographic peaks. Soper et al. have investigated on-the-fly fluorescence lifetime detection in HPLC using a MHF phase-modulation spectrofluorometer, which eliminates the problem of multiple injection and offers other advantages as well. These authors showed that the MHF data acquired on-the-fly during a single chromatographic run contained all the information needed to determine the eluent excited state fluorescence intensity decay kinetics and to indicate and resolve overlapping peaks at intervals as short as several milliseconds. This allowed essentially continuous monitoring of the intensity decay kinetics and static emission intensity during chromatographic elution. This work demonstrated accurate lifetime detection and peak resolution for simple mixtures of PAHs by HPLC. This technique can be used for component identification, indication of coeluting peaks, matrix effects or impurities, and resolution of overlapping peaks. This technique also requires no a priori assumptions about spectral features, chromatographic peak shapes, or fluorescence lifetimes.

Soper et al. investigated the dynamic (on-line) measurement of excited state fluorescence lifetimes for several chromophores separated by free solution CE using time-correlated single-photon counting with NIR (near-infrared) excitation. The chromophores used in this work were tricarboxylic acids that show absorption and emission properties in the NIR and possess excited state lifetimes between 500–1000 ps. The instrument used for this study consisted of a solid-state, passively mode-locked Ti-sapphire laser for excitation and a single photon avalanche diode detector operated in a Geiger mode (Figure 8). The instrument response function of this device was 165 ps fwhm, appropriate for making subnanosecond lifetime measurements in CE applications. The authors demonstrated electrophoretic separation of two NIR dyes, DTTCl (cationic) and IR-125 (anionic), in a 95:5 methanol:water running buffer (pH = 9.5). The excited state fluorescence lifetimes were calculated using maximum likelihood estimators (MLE) methods. At a loading level of 1.42 zmol for IR-125 and 49 zmol for DTTCl, the excited state fluorescence lifetime values were determined to be 482 ± 14 ps for IR-125 and 943 ± 23 ps for DTTCl, which agreed favorably with the values determined for these dyes at high concentrations in static solutions. To demonstrate the feasibility of making excited state fluorescence lifetime determinations in capillary gel electrophoresis, where the gel can produce high scattering backgrounds, the excited state fluorescence lifetimes of C-terminated fragments (produced from the M13 mp 18 template labeled at the 5’ end of a universal M13 sequencing primer with a NIR fluorescent tag) were determined. The mean excited state fluorescence lifetime for 30 different peaks in the electropherogram was 581 ps and the standard deviation was 9 ps.

On-the-fly frequency domain fluorescence lifetime detection in CE was demonstrated by Li and McGown. Virtually continuous detection was achieved by interfacing a commercial CE instrument with a commercial MHF instrument. These authors modified the CE capillary cartridge to allow the capillary to pass through
Figure 8  NIR time-correlated single-photon counting instrument used for excited state fluorescence lifetime determinations in a CE experiment. (Adapted from Smalley et al.)

a specially constructed capillary column mount capable of being micropositioned within the MHF sample chamber. Fluorescence intensity and intensity decay data were recovered from the dynamic MHF data. These data were analyzed using conventional nonlinear least squares or the MEM. The latter method allowed these authors to recover the intensity decay kinetics without a priori knowledge of the system decay function.

7 CHARACTERIZATION OF ORGANIZED MEDIA

Microheterogeneity has been observed in a variety of chemically and biologically organized systems, such as normal and reverse micelles, lipid vesicles, ion-exchange membranes, and cyclodextrins. Applications of time-resolved fluorescence spectroscopy toward the investigation of such systems are widespread. Huang and Bright examined the microenvironments within sodium dodecyl sulfate (SDS) micelles by using two fluorescent probes, 2-anilinonaphthalene-6-sulfonic acid (2,6-ANS) and N-phenylnaphthylamine (1-AN). The excited state intensity decay kinetics were recovered by multifrequency phase and modulation measurements and analyzed using a global analysis protocol. The results showed that the fluorescence intensity decay kinetics of 2,6-ANS, which probes the outer core region (i.e. the palisade layer) of SDS micelles, was characterized by a unimodal Lorentzian lifetime distribution. In contrast, a single discrete excited state fluorescence lifetime was observed for 1-AN, which positioned itself in the micelle inner core region. The intensity decay kinetics of these probes were investigated as functions of temperature, counter-ion (Na⁺ and Mg²⁺) concentration, and linear alcohol cosolvents (n-butanol, n-pentanol, n-hexanol, and n-heptanol). Their collective results confirmed that the outer-core region of SDS micelles is microheterogeneous while the inner-core is essentially homogeneous. In addition, the intensity decay kinetics and the outer-core probe, 2,6-ANS, partitioning appeared to be more sensitive to variations in temperature and counter-ions in comparison to those of the inner core probe, 1-AN. The authors proposed that this observation was a result of different degrees of water penetration in the outer-core region. In the SDS system, the effects of micelle polydispersity and compositional diversity on the environmental microheterogeneity of the fluorescent probe seem to be minimal in comparison to water gradient effects.

Water immobilization at surfactant interfaces in reverse micelles has been investigated extensively. For example, several research groups have examined the dynamical response of water in aerosol OT (AOT) reverse micellar systems. Zhang and Bright investigated the reorganization of water within AOT reverse micelles on the nanosecond timescale using fluorescence spectroscopy of 1,8-anilino-8-naphthalenesulfonic acid (ANS). For water loading \( w_0 < 2.5 \) \( (w_0 = [\text{water}]/[\text{AOT}]) \), they observed two relaxation processes with time constants of 0.5–1.7 ns and 3.5–11.8 ns that they attributed to “free” and “bound” water reorganization,
bulk-like surface of high curvature and that the molecules appear owing to the strong interactions with the polar headgroup molecules near the surfactant interface were ice-like fluorescence of ANS and suggested that the water also probed the AOT interior using resolved fluorescence up-conversion spectroscopy. Sarkar et al. performed time-resolved fluorescence measurements of the probe coumarin 480 in micellar solutions and observed fluorescence decays with time constants ranging from 1.7–12 ns. They also attributed these dynamical changes to relaxation processes of water molecules in various water pool environments. Mittleman et al. used ultrafast spectroscopy to probe the dielectric relaxation of water in AOT reverse micelles. These authors found that the timescale and relaxation amplitude are smaller than those of bulk water. This result was explained in terms of reduced long-range collective behavior resulting from the small water pool in the reverse micelles. Levinger et al. investigated the mobility of water in water/AOT/isooctane reverse micelles by using polar solvation dynamics measurements using ultrafast, time-resolved fluorescence up-conversion spectroscopy. The major results of their work revealed that interactions of water with the surfactant headgroups in AOT reverse micelles effectively eliminates bulk-like solvent dynamics. This was most evident for very small reverse micelles, $w_0 < 5$. As the water pool volume increased in the AOT reverse micelles, more and more water molecules became free to move. This was manifested in a dynamic relaxation event on a timescale comparable to that of bulk water. However, although the solvation dynamics in the largest reverse micelles revealed a considerable fast relaxation component, the overall dynamics were still slower than that observed for bulk water. This suggests that solvent motion within a reverse micellar environment is affected by the surfactant interface.

Characterization of short-lived intermediates in microheterogeneous systems has been carried out by Whitten et al. using time-resolved spectroscopic techniques. The intensity decay kinetics for a series of trans-stilbene-derivated amphiphiles, which readily form bilayer systems in aqueous media, were analyzed by using a lifetime distribution analysis. The results indicated that the observed fluorescence originates from different types of excited state species that consist of two or more trans-stilbene units; one emission feature was attributed to the excited state of a ground state aggregate while the other was assigned to an excimer that may arise from a “defect” in the bilayer. The complex exponential nature of the decay kinetics was attributed to distributions of environments experienced by the fluorescing species.

Dimer formation of naphthalene in Langmuir–Blodgett (LB) monolayer films was probed by time-resolved fluorescence spectroscopy by Yamazaki et al. Naphthalene incorporated in LB monolayer films exhibited two types of fluorescence emission due to monomer and dimer species. The dimer fluorescence corresponded well to that observed in the naphthalene crystal under extraordinarily high pressure and in naphthalene para-cyclophanes. These researchers also reported on the excitation energy relaxation in LB films with rhodamine B, oxacyanine, and pyrene by means of picosecond time-resolved fluorescence spectroscopy. They found that the LB film is characterized by: (1) an inhomogeneous distribution of guest chromophores with fractal or fractal-like structures, (2) the formation of dimers and/or aggregates of dyes in molecular cages compressed within the fatty acid matrix, and (3) excimer formation from the preformed dimers. Their experimental results indicated that naphthalene chromophores were distributed within the LB monolayer films randomly as expected from statistical calculations. Further, naphthalene in LB films of low and medium concentrations (<10 mol%) was dispersed uniformly and randomly as monomer much more than for pyrene or ionic dyes like oxacyanine and rhodamine B, in which cases even low concentrations (1 mol%) resulted in dimer and/or excimer formation.

Cycloextrinsics have drawn significant attention over the last few decades primarily because of their simplicity and the utility of these systems as models for protein–ligand and enzyme–substrate binding. In earlier work, Bright et al. presented nanosecond and picosecond time-resolved fluorometric studies of fluorophore-$\beta$-cyclodextrin inclusion complexes. They found that the recovered intensity decay results for various anilino-naphthalenesulfonate ANS probes (2,6-ANS, 2,7-ANS, 2,8-ANS, and 1,8-ANS) with $\beta$-cyclodextrin are not well described by single or double exponential decay models. Their experimental data demonstrated that the fluorescence intensity decay kinetics of ANS-$\beta$-cyclodextrin inclusion complexes are modeled most accurately by Gaussian or Lorentzian lifetime distributions. In turn, this indicates that there is an ensemble of similarly formed ANS-$\beta$-cyclodextrin complexes in coexistence. This, the authors proposed, arose from rapid exchange between free and cycloextrin-bound ANS complexes.

Wirth and Burbage used frequency domain fluorescence anisotropy decays to characterize the adsorbate reorientation and dynamics at a water/(octadecysilyl)silica interface. These authors showed that one can...
independently study the fluorophore rotational reorientation in the surface plane can be studied independently as well as rotations out of the surface plane. Acridine orange, the fluorescent probe used in this work, exhibited hindered rotational reorientation for its out-of-plane rotation and it rotated slowly in the surface plane. The authors suggested that acridine orange resides at the interface of water and octadecylsilane and it senses the local morphological changes at this interface.

Montgomery and Wirth also investigated the effects of SDS surfactant concentration, above and below the SDS critical micelle concentration (CMC), on the rotational reorientation dynamics of a hydrophobic probe, 1,4-bis[O-methylstyril]benzene, in a monolayer of covalently bonded dimethyloctadecylsiloxane chains. The results showed that for any level of added SDS, the probe reorientation was less hindered than that measured for a pure water mobile phase. The net effect of SDS was to make the hydrophobic environment on the surface more fluid. However, near the SDS CMC, unusual behavior was observed and the probe rotational motion was even less hindered than it was above or below the CMC.

The adsorption of premicellar SDS onto methylated (C₁) silica surfaces was also studied to explore the possibility of monomer physisorption at an interface. Methylene provided a hydrophobic surface precluding SDS chain interpenetration into the methyl monolayer. The premicellar adsorption maxima were found to be smaller for the C₁ surface than for the n-octadecylsiloxane (C₁₈) surface. This implicates interpenetration as an important factor in premicellar adsorption maxima. Surface roughness was also found to increase the premicellar adsorption maximum on the C₁ surface. The rotational reorientation behavior of acridine orange on these surfaces points to a structural transition in the adsorbed SDS layer as the origin of the large premicellar adsorption maximum of SDS on C₁₈.

8 FLUORESCENCE LIFETIME IMAGING MICROSCOPY

Fluorescence microscopy is an indispensable tool in the biosciences because of the excellent detection limits and the environmental responsiveness of selected probes and stains. However, steady-state microfluorimetry is inherently limited because it is more difficult to deconvolve the contributions from multiple “emissive” species, including autoluminescence from intrinsic cellular components, Raman scatter, and quantification problems exacerbated by difficulties in measuring quantum yield profiles across a substrate. In contrast, fluorescence lifetime imaging microscopy (FLIM) does not suffer from the inherent drawbacks of steady-state techniques and provides a means of acquiring information on the organization, structure, and dynamics of complex tissues, cells, and subcellular structures.

In FLIM, the spatial (two- or three-dimensional) distribution of fluorescence decay times are determined directly at every pixel of an image simultaneously. The high temporal and spatial resolution is extremely important because it allows dynamic environmental parameters to be monitored in a spatially defined manner in the specimen under study (e.g. a single living cell). The intrinsic molecular information provided by dynamic measurements also minimizes background concerns and, as the excited state fluorescence lifetime is the only physical attribute observable, the resulting image is, in effect, simplified and filtered to include only the most analytically useful information. Judicious use of fluorescent reporter groups which exhibit excited state lifetime changes when challenged by specific intracellular factors allows one to quantitate such things as environmental membrane potential, temperature, dipolarity, and metabolic chemistries (H⁺, K⁺, Ca²⁺, Zn²⁺, O₂, glucose). The fluorophore/macromolecule mobility can also be assessed and information obtained at the nanometer level using resonance energy transfer techniques.

Since it was first demonstrated in 1990 by Wang et al. that spatial variations in fluorescence lifetimes could be used as a source of image contrast, FLIM has received considerable attention as a powerful noninvasive method for obtaining spatially resolved information at the subcellular and even the molecular level. With state-of-the-art instrumentation, the total data acquisition time required to obtain a FLIM image with the diffraction-limited spatial resolution is typically ~30 s allowing the acquisition, processing, and display of fluorescence lifetime-resolved images in quasi-real time. Although this timescale is rapid enough for many applications, efforts are currently underway to complete this task in less time. Rapid, real time data acquisition would create new possibilities in areas including lifetime imaging endoscopy, large scale medical prescreening and diagnosis, pharmaceutical and medical microplate assays, combinatorial library evaluation, tracking biochemical kinetics, and tracing metabolic pathways.

Great advances in the ability to study dynamic events by FLIM were made by Schneider and Clegg. These authors reported a new instrument capable of acquiring and displaying a time-resolved image in under 200 ms. Gratton et al. have also reported on a scanning fluorescence microscope using an asynchronous pump–probe approach which provides improved spatial
resolution compared to conventional one-photon fluorescence microscopy.\(^{(74)}\) Lakowicz et al.\(^{(75)}\) demonstrated the suitability of phase supression techniques to FLIM for minimizing the contribution from a particular decay time (i.e. species). For example, in the phase-resolved difference image, acrylamide-quenched Yt-base emission was nulled leaving only a residual signal from Yt-base present in inaccessible (unquenchable) environments. Lakowicz et al. were also the first to produce a fluorescence lifetime-based cellular chemical profile by tracking intracellular Ca\(^{2+}\) concentration in COS cell lines using the probe Quin-2.\(^{(76)}\)

Although in its infancy, advances such as these in concert with rapid improvements in laser sources, electronic modulators, intensified CCD (charge coupled device) array detectors, computer processing algorithms, and bioreagents (monoclonal antibodies, nucleic acid probes, fluorescent labels) are sure to make FLIM a more accessible, popular, and routine technique in the analyst’s arsenal.

9 FLUORESCENCE LIFETIME-BASED SENSING

Fluorescence-based sensing can rely on intensity, intensity ratio, or excited state intensity decay kinetics measurements. Although simple in concept and instrumentation, fluorescence intensity based sensing can be confounded by several factors. Frequent recalibration and other corrections are thus required because the fluorescence intensity depends on excitation intensity, light losses in optical fibers, photobleaching, and changes in the light scattering and/or sample absorption characteristics.\(^{(77–84)}\) Wavelength-ratiometric fluorescent probes avoid some of these problems, however, lack of known and systematic methods to create such probes as well as limited commercial availability has hindered the widespread use of this approach. Because excited state fluorescence lifetime measurements are insensitive to probe concentration, photobleaching, washout and excitation instabilities, lifetime-based methods offer new opportunities for chemical sensing. Additionally, application of fluorescence lifetime-based sensing to remote monitoring with fiber optics renders recalibrations and corrections needed with intensity measurements unnecessary.\(^{(77–85)}\)

Fluorescence lifetime-based sensing can be based on various molecular level physical or chemical processes and approaches such as collisional quenching, energy transfer, lifetime-based sensing using intrinsic versus conjugated probes, and so on.\(^{(76)}\) For example, Draxler and Lippitsch have developed an optical pH sensor based on different fluorescence decay times of acid and base forms of the indicator diethylaminomethylpyrene.\(^{(79)}\) The fact that the amino group is decoupled from the chromophoric system, excited state electron transfer probability from the amino group to pyrene influences the fluorescence decay times. This pyrene-based indicator was sequestered within a polyurethane-based hydrogel matrix providing the aqueous environment necessary for the acid–base reactions. The sensor has a favorable pK\(_a\) value (viable over the entire physiological pH range), an acceptable response time, and low cross-sensitivity against other cations. According to the researchers, reproducibility and long-term stability are the exceptional properties of this sensor.

Szmacinski and Lakowicz measured the pH-dependent fluorescence decay times of the seminaphthofluoresceins (SNAFL) and seminaphthorhodafluors (SNARF) using frequency domain fluorometry and an inexpensive 543 nm He–Ne laser light source.\(^{(80)}\) They found that phase and modulation values were strongly dependent on pH in the physiological pH range as well as on the excitation and emission wavelengths. This dependence allows the range of pH sensitivity to be chosen by selection of wavelength(s) and enables increased precision of pH measurements by use of phase and/or modulation measurements at several wavelengths.

Recently, Chang et al.\(^{(81)}\) developed a fluorescence lifetime-based sensor for water, by immobilizing a solvent-polarity-sensitive fluorescent metal−ligand compound, dipyridol[3,2-a:2′,3′-c]phenazine, di[[cis-1,2-bis(di-phenylphosphino)ethylene]osmium(II)] hexafluorophosphate by ionic bonding onto a carboxymethyl cellulose cation-exchange resin, sandwiched between a thin sol–gel-processed layer and a glass substrate. When this solid film sensor is inserted from a water-free into a water-containing organic solvent, a decrease in fluorescence lifetime was observed due to fluorescence quenching. Because of the long decay time of this compound the frequency domain measurements could be performed using an inexpensive amplitude-modulated commercial blue LED. For example, the sensor exhibited a 39.6° phase angle decrease at a 2 MHz modulation frequency when placed from anhydrous acetone into a mixture of 20% (v/v) water in acetone. Similar observations were noticed in five other organic solvents upon addition of water. For this sensor, the response and recovery were both complete within seconds and the detection limit was solvent dependent. With ethyl acetate, the detection limit was as low as 0.02% (v/v) of water. This sensor also displayed excellent long-term stability with little drift in performance after a period of two months. Based on similar principles and instrumentation, these researchers designed a fluorescence lifetime-based sensor for methanol.\(^{(82)}\)
The solvatochromic dye used in this case was tris(4,4′-dicarboxy-2,2′-bipyridine)ruthenium(II) hexafluorophosphate which was dissolved in a PMMA solution to form a thin film in a similar manner as in the case of the water sensor.

Birch et al. have demonstrated an optical method for the selective detection of Cu(II) ions in water using time-resolved fluorescence resonance energy transfer from the xanthene dye rhodamine 800 encapsulated in a Nafion-based sensor platform. They showed that fluorescence quenching of the probe rhodamine 800 by other potentially interfering metal ions such as cobalt, nickel, and chromium were negligible in comparison to copper. They used a 670 nm picosecond diode laser as the excitation source and time-resolved single-photon counting for detection. They were able to determine Cu(II) between 5 and 50 mM. They estimated that the lower limit of detection for the sensor was 10 ppb.

Fluorescence lifetime-based biosensing of zinc was demonstrated by Thompson and Patchan by using frequency domain fluorescence and 5,1-dansylamide as the probe. Briefly, the fluorescence lifetime of the bound dansylamide inhibitor increased approximately sevenfold and the emission was blue shifted 100 nm relative to the corresponding values for the free probe. The carbonic anhydrase/dansylamide indicator system permitted measurement of zinc concentration range over more than three decades.

Draxler and Lippitsch investigated the influence of the microenvironment on the fluorescence behavior of indicator molecules during lifetime-based sensing. The two examples discussed were for a pH sensor using a pyrene-based fluorophore sequestered within a hydrogel and a ruthenium complex for oxygen sensing embedded in a polystyrene membrane. The interactions of a luminophore with a polymer matrix influence its luminescence decay properties. In many cases, deviations from a single-exponential decay could be observed, which may be due to spatial nonuniformity in the matrix refractive index, variations in the chromophore steric stabilization by the polymer environment, or nonresonant energy transfer from the luminophore to acceptor sites within the matrix. These authors also showed that this nonresonant energy transfer leads, at least in the case of a homogeneous distance distribution between luminophores and quenching sites, to a simple mathematical description of the luminescence decay which needs only one additional parameter. They proved the suitability of this approach in experimental assessment with these two different luminophores each in a different polymer. For the examples given, the proposed model gave a physically reasonable and more tractable procedure for evaluating luminescence decay kinetics when compared to multiple-exponential or rate-distribution models.

10 MULTIPHOTON EXCITED FLUORESCENCE

The high peak powers available from picosecond and femtosecond lasers can result in multiphoton excitation, wherein the fluorophore simultaneously absorbs two or more long wavelength photons to yield an excited single state. Multiphoton excitation requires high peak powers to increase the probability that two or more photons are simultaneously available within a given molecular volume for excitation. Because of the interactions of two or more photons with the fluorophore, the selection rules governing these transitions are different from those for one-photon excited fluorescence. The interest in multiphoton excitation has increased dramatically as the result of its applications to time-resolved fluorescence and fluorescence microscopy. Several research groups have demonstrated time-resolved multiphoton excited fluorescence in the time and frequency domains as a tool for determining excited state anisotropy and intensity decay kinetics. Two-photon induced time-resolved fluorescence has been observed for a wide variety of biochemical fluorophores, including membranes labeled with 1,6-diphenyl-3,4,5-hexatriene, labeled DNA, and proteins. Two-photon excited fluorescence lifetimes and rotational reorientation times from those for one-photon excited fluorescence. The primary advantages associated with the frequency domain methodology are its high accuracy and the speed with which the phase angle and demodulation factor can be measured.

Bright et al. reported on the performance of a new multiharmonic frequency domain instrument that uses the high harmonic content of a passively mode-locked pulse-picked femtosecond Ti:sapphire laser as the excitation source for the determination of one-, two-, or three-photon excited time-resolved fluorescence anisotropy and intensity decay kinetics. The new instrument uses a parallel data acquisition strategy which allows complete frequency domain data sets to be acquired in as little as 30 s. They demonstrated the potential of this new instrument by measuring the excited state fluorescence lifetimes and rotational reorientation times for fluorophores and fluorophore mixtures that exhibit nanosecond and subnanosecond single exponential and multiexponential decay kinetics under one-, two-, or three-photon excitation. The instrument was able to recover the fluorescence decay kinetics accurately and offered a measurement precision on the order of 5–10 ps. The

multifoton induced anisotropic fluorescence using TCSPC techniques confirm that a higher degree of molecular orientation for two- and three-photon excitation is obtained in comparison to one-photon excitation. Multiphoton excitation, therefore, suggests itself as a more sensitive means of acquiring fluorescence anisotropy decays when probing the dynamics and structure of nanoscale microheterogeneous systems such as biomembranes, porous sol–gel glasses, and molecular matrices by observing molecular rotation of the fluorophore. Moreover, time-resolved multiphoton induced fluorescence studies using TCSPC offer potential in other applications, such as nonlinear fluorescence microscopy.

Saturated hydrocarbons, including linear, branched, and cyclic alkanes, are known to fluoresce when excited in the vacuum ultraviolet near 140–160 nm. These saturated hydrocarbons display emission from 200–240 nm, which could readily be transmitted by quartz optics. Vacuum ultraviolet excitation conditions are incompatible with biochemical and biophysical experiments because it is necessary to exclude oxygen which strongly absorbs below 250 nm. They also require the use of special optics which transmit the vacuum ultraviolet excitation. Lakowicz et al. have demonstrated that saturated alkanes can be excited with two-photon excitation allowing frequency domain fluorescence spectroscopic measurements. Recently, Lakowicz et al. observed fluorescence emission from 2,5-diphenyl-1,3,4-oxadiazole (PPD) resulting from two-photon excitation with two different wavelengths near 380 and 760 nm. The two-color two-photon (2C2P) induced emission was observed when the PPD sample was illuminated with both wavelengths, but only when the picosecond laser pulses were spatially and temporally overlapped. For 2C2P excitation, the time zero anisotropy was larger than possible for single-photon excitation and was consistent with collinear electronic transitions for both wavelengths. The intensity depended on the polarization of each beam in a manner consistent with collinear transitions. Their results demonstrate that 2C2P excitation can be readily observed with modern laser sources. This phenomenon is suggested to have numerous applications in the chemical and biomedical sciences, as a method for spatial localization of the measured volume.

**11 SUMMARY AND FUTURE PROSPECTS**

In this article, we have highlighted the applications of excited state fluorescence anisotropy and intensity decay measurements in several areas that we view as being of interest to the analytical community. Continued technological advances in excitation sources and detection electronics coupled with the development of long-lived red-NIR fluorescent dye chemistries are crucial for the practical application of time-resolved fluorescence to further applications as well as in facilitating transfer of this powerful technique to routine analysis (e.g. environmental, toxicological, clinical, and chemical process monitoring). Eventually, such advances in time-resolved fluorescence may result in a new generation of commercially viable clinical and medical devices (e.g. sensors) for use in the clinical laboratory or during office visits, at the patient’s bedside, and even in home health care.
By way of example, measurement of excited state fluorescence intensity decay kinetics of saturated linear and cyclic alkanes following two- or multiphoton excitation opens up new avenues to probing molecular systems. Alkyl groups can be regarded as intrinsic fluorophores present in all macromolecules and emission from alkyl groups can be expected whenever they are in a nonpolar environment shielded from contact with the dipolar media. For instance, such aliphatic side chains of detergents and lipids may serve as intrinsic fluorescent probes of micelles and bilayers.

Finally, it should be noted that this article is by no means comprehensive. Within subsections, references were chosen to demonstrate particular recent areas of application or to highlight novel achievements. As such, they are in an academic sense representative of the types of research that have been conducted in this field in the 1990s.

An overview is given of existing indirect detection methods of inorganic and organic anions in capillary zone electrophoresis (CZE). Kohlrausch’s regulating function (KRF), used by several researchers to predict the detection sensitivity of ultraviolet (UV)-inactive analytes in CZE, is reviewed. Sensitive indirect photometric detection (IPD) of ionic compounds in CZE is largely governed by the value of the change in absorbance in a solute zone. This in turn depends on a transfer ratio (TR), ratio of the charge, and ratio of the electrophoretic mobility of the analyte and IPD reagent. The influence of other experimental parameters, such as pH, type and concentration of the absorbing electrolyte, detection wavelength, and absorption pathlength, on detection sensitivity are also critically discussed. An extensive part of this review deals with the separation of various classes of...
ionic analytes using capillary zone electrophoresis/indirect photometric detection (CZE/IPD). Different approaches for simultaneous separation and indirect detection of nonabsorbing anions and cations are evaluated. From this evaluation, some rules of thumb as to when these approaches will be most effective are drawn. In addition, indirect fluorescence detection (IFD) in CZE and micellar electrokinetic chromatography (MEKC) are reviewed and possible application areas are highlighted. Some recent developments in other indirect detection modes, such as indirect chemiluminescence detection (ICLD) and indirect conductivity detection (ICD), are outlined.

1 INTRODUCTION

Direct detection employed in capillary electrophoresis (CE) refers to a situation where the eluent or electrolyte has a lower value of the measured physical property (i.e. absorbance, fluorescence, chemiluminescence, conductivity, amperometry), whereas indirect detection refers to a reverse condition. These two situations are shown schematically in Figure 1 for photometric detection. Indirect detection methods have been used in both ion chromatography (IC) and CE for mostly ionic species whose structure lacks the measured physical property for direct detection. These detection methods are universal in applicability and can be used with all detectors that are normally used to measure the analyte signal in a direct detection mode. Thus, indirect detection is applied to a wide variety of compounds without the need for pre- and postcolumn derivatization.

The first report dealing with the use of indirect detection in CZE for the analysis of ionic species was demonstrated more than 10 years ago by Hjerten et al. This was followed by a report by Foret et al. in 1989. Currently, it is an active area of research in CE for a variety of ionic compounds. Accordingly, this article provides a critical review dealing with the IPD and IFD methods of ionic species separated by CZE. All publications that have appeared in abstracted journals up until April 1999 are summarized. In addition, IFD of neutral species after their separation by MEKC is discussed. Only three communications on indirect chemiluminescence and three on indirect electrochemical (amperometry, conductivity) detection have been published, to my knowledge, since the beginning of 1990; therefore these indirect detection modes are discussed briefly.

1.1 Indirect Photometric Detection in Capillary Zone Electrophoresis

The real interest in the use of CZE with IPD, especially for inorganic ion analysis, started with the work of Jones et al. in the early 1990s. At present, this is the most popular indirect detection mode in CZE analysis of a variety of inorganic and organic ions, and is discussed comprehensively in recent review articles.

1.2 Theory and Operating Principle

In CZE, indirect absorbance detection (also known as IPD) has been used for ionic species whose structure lacks the absorbance properties for direct detection. The key element for IPD in CE is to maintain a large continuous background absorbance signal at the UV detector by employing a chromophoric ionic species (an ion with the same charge as the analyte) in the carrier electrolyte. If the concentration of this light-absorbing species remains constant in the electrical double layer in the CE column, a steady level of background absorbance translated as a stable baseline is displayed on the electropherogram. When a non-UV-detectable ionic species passes the detection window, charge displacement of the chromophoric ion leads to a quantifiable decrease in the background absorbance. This translates to a negative peak; however, leads on the data acquisition system can be
switched to record signals as a positive peak. Similarly to IC, sensitive IPD of ionic species is possible in CZE mode because of the charge displacement that occurs in the electrical double layer of the bare fused-silica capillary. However, in CZE this charge displacement is enforced not by the ion-exchange groups as in IC, but by a fixed and oppositely migrating flux of counterions and by the requirement of electroneutrality.

1.3 Detector Response Equation

The concentration limit of detection \( C_{\text{LOD}} \), in moles per liter, for a nonabsorbing analyte detected using IPD can be expressed as a function of the concentration of the UV-absorbing species \( C_M \), the TR, and the dynamic reserve (DR), according to Equation (1):\(^{(14,15)}\)

\[
C_{\text{LOD}} = \frac{C_M}{\text{DR} \cdot \text{TR}} = \frac{N_{\text{BL}}}{\text{TR} \cdot \epsilon l}
\]

where \( N_{\text{BL}} \) is the baseline noise, \( \epsilon \) is the molar absorptivity of the IPD reagent, and \( l \) is the pathlength of the detection cell. The DR is defined as the ability to measure a small change on the top of a large signal, and is equal to the ratio of the background absorbance to noise. The TR is defined as the number of moles of the IPD reagent displaced by one mole of the analyte. For example, TR values of 1 and 2 are possible when respective ions Cl\(^-\) and SO\(_4^{2-}\) are displaced by naphthalene-1-monosulphonate (NMS). Briefly, the TR predicts that, everything else being the same, the molar sensitivity of divalent ions is going to be twice that for monovalent ions. However, in reality a mobility match in CZE can offset such effects. Equation (1) also predicts that \( C_{\text{LOD}} \) can be improved by reducing \( C_M \) or by increasing the DR. Because the DR is also related to \( C_M \), decreasing the concentration of the absorbing species (IPD reagents) will not necessarily improve the limit of detection (LOD). This is because the DR is also decreased, and electrophoretic dispersion in CZE can result in a poor LOD for nonabsorbing analytes. Hence, improving \( C_{\text{LOD}} \) often requires maximizing the DR by either reducing the background noise or increasing the background absorbance of the IPD reagent. Nevertheless, it can be concluded that all three parameters \( C_M, \text{DR} \) and \( \text{TR} \) of Equation (1) are not necessarily independent and an operator needs to optimize them to achieve the best possible detection limits. It is worth mentioning that \( C_{\text{LOD}} \) values for IPD of around \( 10^{-4} - 10^{-5} \) M are routinely achieved in CZE.\(^{(16)}\) The best \( C_{\text{LOD}} \) in IPD is obtained using a double-beam laser-induced diode detection, for which the \( C_{\text{LOD}} \) is about \( 10^{-7} \) M.\(^{(17)}\) These systems typically reduce the noise level by an order of magnitude.

1.4 The Transfer Ratio and Kohlrausch’s Regulating Function

As discussed earlier, the extent of displacement of the light-absorbing co-ion by the analyte is known as the TR. According to Equation (1), \( C_{\text{LOD}} \) is inversely proportional to the TR. Thus, a higher value of TR results in a large analyte peak area and a decrease in the \( C_{\text{LOD}} \) term. In addition, Equation (1) predicts that a TR between a singly charged analyte and the IPD co-ion would be unity. This means that peak areas for analyte ions of the same charge and concentration should be similar, which enables one to perform a universal calibration. However, Ackerman et al. called attention to the fact that a nonlinear relationship existed between peak areas and effective mobilities.\(^{(15)}\) These researchers explained their results by considering KRF, also abbreviated as “\( w \)”. This function \( w \) is generally written according to Equation (2):

\[
w = \frac{C Z_i}{\mu_i} = \text{Constant}
\]

where \( Z_i \) represents the absolute charges, \( \mu_i \) the absolute values of effective mobility, and \( C \) the molar concentrations of all ionic species. In addition, note that negative ions have negative \( \mu \) and \( z \) values, whereas positive ions have positive \( \mu \) and \( z \) values.

After the sample ion B is injected and the voltage is applied, a volume element of the capillary, which is originally filled with IPD reagent AC (A = UV-absorbing co-ion; \( C = \) non-UV-absorbing counterion) at a concentration \( C_A \), will consist of a mixture of both co-ion A and the solute ion B for a while. However, the original situation will be restored very soon. Ackerman et al.\(^{(15)}\) gave the expression shown in Equation (3) for the migrating sample ions in this case:

\[
C_A^C = C_A + C_B^S
\]

The superscripts C and S in Equation (3) refer to the concentrations of the IPD electrolyte zone and the solute zone respectively. According to Nielen,\(^{(19)}\) Cousins et al.,\(^{(20)}\) Buchberger et al.,\(^{(12)}\) and Klampfl et al.,\(^{(21)}\) Equation (2) can be verified from Kohlrausch theory according to Equation (4):

\[
k_B = \text{TR} = \frac{Z_B \mu_A (\mu_B + \mu_C)}{Z_A \mu_B (\mu_A + \mu_C)}
\]

where \( k_B \) is referred to as the TR (also called the response factor); \( Z_A \) and \( Z_B \) represent absolute charges on analyte and the IPD co-ion A, respectively; \( \mu_A, \mu_B \), and \( \mu_C \) refer to the effective electrophoretic mobility of the IPD co-ion (i.e. ions of the same charge as that of the analyte) A, analyte ion B, and the nonabsorbing counterion (i.e.
ions of opposite charge to that of the analyte ion) C. The absorbances of the IPD ion ($A^C$) and the sample ion ($A^S$) can be written in accordance with Beer’s law, as shown by Equations (5) and (6), respectively:

\[ A^C = \varepsilon_A C_A^C l \]  
\[ A^S = \varepsilon_A C_A^S l + \varepsilon_B C_B^S l \]  

From Equation (3), the UV signal generated as a change in background absorbance ($\Delta A$) can be shown according to Equation (7):

\[ \Delta A = A^C - A^S = C_A^S l (\varepsilon_A k_B - \varepsilon_B) \]  

For non-UV-absorbing sample ions, $\varepsilon_B = 0$. Substituting for the TR from Equation (4), Equation (8) was derived:\(^{(12)}\)

\[ \Delta A = C_A^S l Z_A \mu_A (\mu_B + \mu_C) \]  

An important characteristic of Equation (8) indicates that, in an IPD system, the value of $\Delta A$ in a solute zone is proportional to the value of the TR (also known as the response factor, $k_B$), the ratio of the charge of the solute and the light-absorbing electrolyte ion, as well as the concentration of the solute ion. Hence, the values of $\Delta A$ (i.e., the detection sensitivities) for solutes with identical charges and concentrations can be determined by the values of the response factors. The value of $\Delta A$ is negative (i.e., analytes detected as negative peaks) if the running buffer with co-ion $A$ is being used as a light-absorbing ion. In contrast, $\Delta A$ can be either positive or negative depending on the relative mobility of a solute to the nonabsorbing counterion in a system; and absorbing co-ion as the IPD reagent. Additionally, Equation (8) also indicates that when the mobility of the counterion ($\mu_C$) is higher than the mobility of the solute ($\mu_B$), $\Delta A$ will acquire a positive value; and a negative value when $\mu_C$ is lower than $\mu_B$. Furthermore, when a solute ion has the same mobility as the co-ion (which is also a light-absorbing ion), equivalent-per-equivalent exchange can be expected. This charge displacement process improves the peak shape and increases the TR, which in turn provides a better LOD.

A literature survey indicates that several researchers have tested the validity of Equation (8). Nielen\(^{(19)}\) first applied this equation to calculate the response factors of alkylsulfates using veronal as the IPD co-ion. He found the response factors of alkyl sulfates to be consistent with the trend predicted in Equation (8). Cousin et al.\(^{(20)}\) recently determined the TR values for several inorganic anions using chromate, pyromellitate, trimellitate, phthalate and benzoate as IPD reagents. Comparison of TR values for these five reagents indicated that chromate is the best IPD reagent for high-mobility inorganic anions. However, the fit of the experimental data to the calculated data using Equation (8) was poor. Very recently, Doble et al.\(^{(12)}\) observed that the agreement between experimental and theoretical values of TR can be improved if the IPD reagent is free of any interfering co-ions. For example, reformulating the electroosmotic flow modifier (i.e., addition of a tetradeyl-ammonium hydroxide instead of tetradeylammonium bromide) to the IPD electrolyte is beneficial because the hydroxide co-anions are utilized by the buffer.

2 FACTORS INFLUENCING INDIRECT PHOTOMETRIC DETECTION SENSITIVITIES

Theoretical considerations suggest that optimal sensitivity in IPD can be achieved if several conditions are fulfilled. First, the light-absorbing reagent should have a large molar absorptivity and an effective mobility that closely match those of the analyte ions. Second, the concentration of the IPD reagent and type and concentration of the nonabsorbing background electrolyte should be carefully selected. This is because high sensitivity is obtained only if the visualization co-ion is displaced by the analyte ion. Third, the pH of the light-absorbing electrolyte should be such that it minimizes the contribution of non-UV-absorbing H\(^+\) and OH\(^-\) ions during the charge displacement process. For example, at very high pH (pH > 12.1), which is required for the ionization of weakly acidic compounds (e.g., sugars), the signal-to-noise ratio (S/N) in IPD drops sharply.\(^{(23)}\) Fourth, choice of appropriate detection wavelength, low background noise and a long absorption pathlength are also desirable for sensitive detection.

2.1 Molar Absorptivity of the Indirect Photometric Detection Reagent

According to Equation (1), increasing the molar absorptivity $\varepsilon$ of the IPD reagent increases the DR. The advantages of a high-$\varepsilon$ reagent become apparent as one tries to decrease the $C_M$, resulting in improved detection limits. On the other hand, to obtain full benefit of a high-$\varepsilon$ reagent care must be taken to match its mobility to the sample ion. A series of publications dealing with IPD in CZE has considered a high-$\varepsilon$ reagent for optimum sensitivity.\(^{(12,5,20,24–31)}\) For example, using sorbate (a high-$\varepsilon$ reagent) instead of a benzoate (a low-$\varepsilon$ reagent), Foret et al.\(^{(22)}\) achieved a significantly (ca. 50 times) lower LOD. Shamsi and Danielson\(^{(24)}\) investigated a series of
indirect detection methods in capillary electrophoresis

Ribonucleotide reagents for the separation of polyphosphates (Pₙ) and polyphosphonates (RPₙ). Best detection limits for these phosphorus-containing anions were obtained with adenosine 5'-monophosphate (AMP). This reagent provided the highest ε and closest mobility match for Pₙ and RPₙ. Similar results were obtained by Beck and Engelhardt[25] and Weston et al.[26] when comparing a series of cationic IPD reagents for the separation and IPD of inorganic and organic cations. To extend the versatility of IPD reagents in the visible region, Mala et al.[27] investigated methyl green and chlorophenol red as IPD electrolytes for analysis of cations and anions, respectively. These dyes possess ε values an order of magnitude higher than conventional light-absorbing reagents such as chromate or phthalate. However, the reported LOD was not significantly better than those obtained with conventional reagents. Probably the presence of nonabsorbing co-ions competed with absorbing co-ions in the charge displacement, resulting in a less pronounced effect on the sensitivity of IPD.

2.2 Mobility of the Indirect Photometric Detection Reagent

As the sensitivity in IPD is governed by the ε of the carrier electrolyte, so too are its charge and electrophoretic mobility. Mikkers et al.[32,33] were the first to discuss the rules governing the effect of electrophoretic migration on the analyte zone concentration distribution using a nondiffusional model derived from KRF. According to this rule, symmetrical peaks are obtained only when the electrolyte co-ions have a mobility similar to that of the analytes. Electrolyte ions that have a slower mobility than the analytes will exhibit fronting peaks. In contrast, electrolyte co-ions with faster mobility than the analytes result in tailing peaks. Examples of the aforementioned rule were illustrated by Jones and Jandik[34] using three IPD electrolytes: chromate (high mobility), phthalate (intermediate mobility), and p-hydroxybenzoate (low mobility). Figure 2 shows the peak shapes of anions using these three IPD electrolytes. Note that the mobility for each IPD electrolyte is indicated by an arrow and represents the region that results in the most symmetrical peak shapes for analyte ions. Thus, the peak shapes in Figure 2 indicate that chromate has a mobility close to inorganic anions (peaks 1 and 2), phthalate has a mobility close to the carboxylates (peaks 3–5), and p-hydroxybenzoate has a mobility close to short-chain linear alkanesulfonates (peaks 6 and 7).

Shamsi and Danielson[35] used naphthalenesulfonates as IPD electrolytes and investigated the peak shapes for inorganic anions, organic acids and long-chain aliphatic sulfonates and sulfates. Figure 3 shows electropherograms of a standard mixture of seven common inorganic anions with singly charged NMS, doubly charged...
naphthalenesulfonate (NDS), and triply charged naphthalenetrisulfonate (NTS) electrolytes. Although all three electropherograms were run under similar conditions, the analyte peak shapes were very different. With NMS, poor sensitivity and peak fronting were evident, whereas NDS and NTS electrolytes provided almost equally good peak shapes for all seven anions. Note that for the NDS electrolyte, the orthophosphate peak becomes very symmetrical, whereas fluoride gives an excellent peak shape with NTS. These differences in peak shapes for orthophosphate and fluoride are consistent with their respective electrophoretic mobilities of the co-ion and counterion. It is worth noting that the electrophoretic mobility of anions has a negative sign. 

According to Hjerten, the conductivities of the analyte and the running electrolyte. This dependence depends on two factors: the difference in mobility between an electrolyte and the analyte ion; and the absolute difference in the concentration and mobility of the analyte respectively, and \( \mu_{\text{co-ion}} \) and \( \mu_{\text{counterion}} \) are the respective electrophoretic mobilities of the co-ion and the counterion. It is worth noting that the electrophoretic mobility of a cation usually has a positive sign, whereas the electrophoretic mobility of anions has a negative sign.

**Figure 4** Comparison of naphthalenesulfonate electrolytes for the separation of alkyl sulfates. Peak identification: 20 ppm each of (1) C₁₄SO₄⁻, (2) C₁₂SO₄⁻, (3) C₁₀SO₄⁻, (4) C₈SO₄⁻, (5) C₆SO₄⁻, and (6) C₄SO₄⁻. The electrolyte consisted of 5 mM NMS, NDS or NTS in 100 mM H₂BO₃, 5 mM Na₂B₄O₇, pH 8 buffer. Vacuum injection: 4 s for NMS and 5 s for NDS and NTS; +30 kV applied for separation; current = 8–10 µA. 

**Figure 5** Separation of inorganic cations with imidazole/α-hydroxybutyric acid (α-HIBA) electrolyte. Conditions: 5 mM imidazole/6.5 mM α-HIBA/2 mM 18-crown-6, pH 4.5; 75 mm i.d. × 60 cm capillary; 30-s injection; 20 kV; UV detection at 214 nm. Sample 1 µg mL⁻¹ of each cation. 

UV-absorbing electrolyte in IPD must include the consideration of achieving not only high molar absorptivity, but one with a close mobility match to the sample components. As in the case of anions, several studies have shown that mobility matching is also important for the IPD of cationic solutes. An electropherogram is shown in Figure 5 for the separation of five inorganic cations and ammonium ions using imidazole as the IPD reagent. In this electropherogram, ammonium and potassium exhibit fronting whereas lithium exhibits tailing. Additionally, calcium, sodium, and magnesium show no peak asymmetry, indicating that the imidazole has a mobility close to these cations.
2.3 Concentration of the Indirect Photometric Detection Reagent

The concentration of the IPD electrolyte co-ion is also an important consideration, for two major reasons. First, it is the ratio of the conductivities of the sample and the electrolyte that will control the peak shape; in general, peak efficiency and resolution increase with increasing ratio of the light-absorbing carrier electrolyte concentration to sample concentration. Second, the absorbance detector used in IPD mode shows a linear response range up to 0.20 AU, therefore the maximum concentration of the IPD electrolyte that can be used is the concentration that will give a background absorbance of <0.20 AU. Recent studies by Shamsi et al. indicated that the background absorbance inside the fused-silica capillary can be linear up to ca. 0.5 AU, a value dependent on both the type of IPD electrolyte and the detector optics. The same authors have also studied the effect of increasing the concentration of NDS or NTS reagent on the S/N of some inorganic anions. As shown in Figure 6, sensitivity first tends to increase with the increase in NDS or NTS concentration between 1 and 4 mM, providing sharper peaks and better resolution. With a further increase in concentration, i.e. >4 mM NDS or NTS, a downward trend in S/N is evident. This decrease in S/N is obviously due to an increase in the magnitude of noise, which increases proportionally with increasing concentration of UV-absorbing electrolytes. In addition, the linear response range for the nonchromophoric analytes is strongly influenced by the IPD electrolyte concentration. The use of a higher concentration of IPD reagents will extend the upper linear range of the analyte ion, although at a high IPD electrolyte concentration the background noise and Joule heating also increase, thus decreasing the sensitivity of IPD. In general, most electrolytes used in IPD have concentrations in the range 1–10 mM. This means three orders of magnitude in linearity for the analyte ion. It should be noted that in IPD the running electrolyte concentrations are ca. 10 times less than those employed in CZE with direct UV detection. Therefore, peak distortion due to a mobility mismatch is more critical with indirect than with direct photometric detection.

2.4 Type and Concentration of the Nonabsorbing Buffer

One approach that optimizes electrophoretic separation and IPD of inorganic anions is the use of nonabsorbing co-anionic buffers such as borate, acetate, phosphate, and carbonate. Obvious advantages of these buffer co-anions are high reproducibility, sharper peaks, and rugged separations. In practice, baseline noise at higher ionic strength of the co-anionic buffer results in reduced S/N due to dilution of the zones of the light-absorbing reagent by nonabsorbing co-anions. Moreover, the presence of these co-anionic buffers leads to system peaks that may interfere in the analysis of some inorganic anions. The migration time and S/N of some inorganic anions as a function of borate (H$_3$BO$_3$/Na$_2$B$_4$O$_7$) concentration from 20 to 200 mM has little effect on the migration of anions. However, increasing the concentration of the same buffer anions improved the detection limits by a factor of 2 for low-mobility inorganic anions (e.g. phosphate, fluoride) (Figure 7). In contrast, little effect on...
the S/N of high-mobility inorganic anions (e.g. bromide, chloride, nitrite, and nitrate) was seen. Probably, the mobility of borate anion matches the former more closely than the latter group of anions.

A second approach entails the use of nonabsorbing countercations such as Tris$^{(44-47)}$ and triethanolamine.$^{(48-50)}$ The running CZE buffers are generally prepared by titration of the acid form of IPD electrolyte with the buffering base. Because these running CZE buffers consist of a single co-anion, the charge displacement process is simplified and the S/N remains unaffected.

### 2.5 pH of the Indirect Photometric Detection Reagent

Similarly to ion-exchange chromatography, IPD in CZE is also sensitive to pH extremes. The CZE separations of inorganic cations are mostly performed over the range 3–5. In contrast, anionic CZE separations are rarely obtained at a pH of <7.0. The reason for this is that these inorganic cations and anions, as well as the capillary surface, have different properties at different pH values. For example, at high pH, CZE separations of some metal cations (e.g. transition metals, alkaline earths) are not feasible, due to precipitate formation and interaction of these cations with the negative charge of the fused-silica capillary. Moreover, aromatic bases that are commonly used as IPD reagents for cation separations have $pK_a$ values in the acidic pH range. This means that they are not appreciably ionized at neutral to basic pH values. In view of this, the pH of the running electrolyte should be sufficiently low so that IPD reagent exists as cations with sufficiently high mobility to match the mobility of fast-moving inorganic cations. On the other hand, the selection of pH for the CZE separation of inorganic anions is not as critical. This is because the majority of the inorganic anions are strong acids and hence are completely ionized in neutral to alkaline pH conditions. One exception is the weakly ionized solute (e.g. carbohydrates), which requires a pH approaching 12 to have any appreciable fraction in the anionic form. When choosing pH $>12$, the concentration of the hydroxide ions is no longer negligible relative to the concentration of the IPD electrolyte. Consequently, a decrease in TR generally reduces the IPD signal.

Vorndran et al.$^{(51)}$ first described the use of sorbate as the IPD reagent for the analysis of carbohydrates. A rather simple electrolyte system containing 6 mM sorbate adjusted to pH 12.1 with sodium hydroxide permits the separation of 11 carbohydrates in ca. 20 min. Although resolution of carbohydrates improved with rising pH, the sensitivity of detection decreased considerably above pH 12.1 (Figure 8). Ma et al.$^{(31)}$ investigated the influ-

---

ence of the pH of the phthalate electrolyte on the separation and IPD of four inorganic anions (bromide, chloride, nitrate, and sulfate). At low pH (i.e., pH 4.3), phthalate electrolyte being singly charged has lower electrophoretic mobility, resulting in poor S/N for the high-mobility inorganic anions (Figure 9, spectrum a). Increasing the pH to 6.5 fully ionized the phthalate electrolyte and improved the S/N (Figure 9, spectrum b). Further increase in pH value enhanced the overall resolution of the anions (Figure 9, spectra c and d), but at the expense of longer migration times and peak broadening.

Shamsi and Danielson studied the effect of pH on the detection limits of phosphorus-containing anions using AMP as the IPD reagent. The four electropherograms shown in Figure 10 illustrate that both the S/N and the migration time of $P_n$ and $RP_n$ decrease as the pH is increased from 6.30 to 8.30. However, the overall increase in mobility of these anions is not as much as one would have expected. This is because electroosmotic flow and electrophoretic vectors oppose each other. The increase in baseline noise at pH 8.30 was found to be caused by dilution of the AMP zones by the nonabsorbing co-anions (hydroxide and borate anions). Excessive heating due to an increase in current from $6 \mu A$ at a pH of 6.80 to $13 \mu A$ at a pH of 8.30 resulted in greater mobility of hydroxide ions, and consequently an increase in the baseline noise.

Shamsi and Danielson also compared the theoretical and experimentally determined detection limits of 12 $P_n$ and $RP_n$. The experimentally determined TR ($\Delta T$) was compared with the TR expected on the basis of an equivalent-to-equivalent exchange between the electrolyte and analyte ions. It was shown that there can be situations in which a large TR value for some analytes is less important than a small $\Delta T$ value with respect to the experimental detection limits. Several examples of this situation are shown in Table 1. At a pH of 7.80, $P_2$ phosphate, HDTMP, ATMP, EDTMP, and DETPMP have more favorable $\Delta T$ and TR values than $P_1$ phosphate,

P₁ phosphate, or P₁ hypophosphite. For this reason, the detection limits of the former group of analytes were 2–5 times better than the latter. However, at a lower pH of 6.80 the differences in ΔT and the experimental detection limits between these two groups of analytes were not great. In general, the authors found that a low pH improves the sensitivity but at the same time increases the ΔT values for Pₙ and RPₙ. Because of these two competing factors, the detection limits of some phosphorus anions, such as P₁ phosphate or P₁ hypophosphite, were improved whereas the detection limits of DETPMP became worse. On the other hand, there was not much change in the detectability of HDTMP, ATMP, and EDTMP at pH 6.80 compared to pH 7.80.

2.6 Effect of Detection Wavelength
Another method of optimizing sensitivity is the choice of an appropriate detection wavelength. The largest signal generated for IPD is found where the light-absorbing reagent absorbs most strongly and the analytes absorb the least. In general, most inorganic cations have no UV absorbance at any wavelength. Hence, IPD reagents for inorganic cations can be selected that have strong UV absorbance at wavelengths as low as 185 nm. Figure 11 shows the effect of wavelength on sensitivity and direction of the photometric signal for seven common inorganic anions and organic acids at three different detector wavelengths using NTS as the IPD reagent. Although shorter wavelengths of 214 and 206 nm can improve sensitivity for some nonabsorbing analytes, a more universal detection (i.e. all peaks in one direction) is obtained at a longer wavelength of 284 nm for both inorganic anions and organic acids. Although NTS does have another wavelength maximum at 234 nm, this wavelength was not utilized because the absorbance was outside the Beer’s law working range. Analytes such as nitrite and nitrate, which are UV-absorbing at a wavelength of 214 nm, showed positive peaks but nitrite detectability was not improved because the absorption difference between nitrite and NTS is not great at this wavelength. In contrast, the sensitivity of detection of bromide, nitrite and nitrate can be improved by direct UV detection at a wavelength of 206 nm. In addition, organic acids such as maleate can be detected directly at 206 nm.

* Reproduced by permission from Jones. (Copyright 1993 Elsevier Science N.V.) A negative number indicates that the analyte is more absorbing than the electrolyte. The terms dl and np stand for detection limit and no peak, respectively.
electrolyte provides the strongest background signal at 185 nm, followed by the second and third strongest background signals at 365 nm and 254 nm respectively. As shown in Table 2, 185 nm provided the largest peak height ratio for 9 of 11 inorganic anions, whereas 365 nm had the second and 254 nm had the third largest peak height ratio for at least seven inorganic anions. However, the largest peak height does not necessarily provide the lowest detection limits. This is because the lamp energy can also influence the detector performance. Higher-energy lamps generate more photons per unit time, thus reducing the shot noise. A comparison of lamp output energy at 185, 254, and 365 nm indicated that the mercury lamp operated at 254 nm provided the highest photodiode current (ca. 1.55 nA) and thus the best detection limits for 11 inorganic anions (Table 2).

2.7 Effect of Background Noise

In general, the noise level observed in IPD is higher than in direct detection using the same instrument. Wang and Hartwick\(^{45}\) were the first to study in detail the factors that influence the background noise in IPD. The authors found that the noise in IPD is generated from at least two different sources: the IPD reagent, and the detector electronics. Although the mechanism of noise produced from the IPD reagent was not clear, it appeared to be dependent on the concentration of the IPD reagent, the applied voltage, and the surface modification of the capillary. To improve the \(C_{LOD}\) in IPD, light-emitting diodes have been developed that provide excellent baseline stability and reduced noise level up to one order of magnitude.\(^{54–56}\) However, these diodes require the use of IPD reagents that absorbs light in the visible region. Characterization of a suitable IPD electrolyte in the visible region is problematic for two major reasons: first, chromophores that have intense absorption in the visible region are large organic molecules with lower electrophoretic mobilities that do not match those of the analytes (e.g. high-mobility inorganic anions); and second, the adsorptive interactions of such molecules with the capillary cause baseline fluctuations. Thus, the actual \(C_{LOD}\) in the visible region with light-emitting diodes is no better than the conventional IPD in the UV region.

2.8 Effect of Absorption Pathlength

The influence of detection cell length, \(l\), with the aim of increasing the background noise, has been investigated by several authors. Ma and Zhang\(^{31}\) studied the effect of increasing pathlength by comparing capillaries having different diameters. They observed that the detection limits were about the same when a capillary internal diameter was increased from 25 \(\mu\)m to 75 \(\mu\)m, but Joule heating increased with increasing capillary diameter, resulting in an increase in the background noise. This result is in agreement with the data published by Anderson et al.,\(^{57}\) but is in contrast to the report by Steinar et al.\(^{58}\) in which the S/N increased with an increase in capillary diameter from 10 \(\mu\)m to 1000 \(\mu\)m. Probably in the latter study the background noise level was not measured with the voltage on, and therefore the contribution of Joule heating to noise was insignificant. Weston et al. reported improvement in the IPD signal by a factor of approximately two using a capillary of extended pathlength.\(^{26}\) A 75- \(\mu\)m capillary was extended to 300 \(\mu\)m by blowing a bubble at the detection window. This procedure is very useful because the contribution of Joule heating to the background noise is negligible due to the capillary diameter being unchanged for almost the entire capillary length.

3 DETERMINATION OF ANIONIC AND CATIONIC COMPOUNDS

Detection of nonchromophoric anions and cations in CZE is usually accomplished using anionic and cationic chromophoric reagents, respectively. Tables 3–10 list typical carrier electrolytes that are compatible for IPD of anionic and cationic solutes. These compounds can be classified into groups as shown and discussed below:

1. IPD of inorganic anions (Table 3);
2. IPD of inorganic cations (Table 4);
3. IPD of short-chain organic acids and amines (Table 5);
4. IPD of long-chain fatty acids (Table 6);
5. IPD of inorganic and organic phosphates (Table 7);
6. IPD of long-chain aliphatic anionic and cationic surfactants (Table 8);
7. IPD of carbohydrates (Table 9);
8. IPD of amino acids and phospholipids (Table 10).

3.1 Indirect Photometric Detection of Inorganic Anions

As discussed earlier, IPD was probably used for the first time in CZE by Hjerten et al. in 1987\(^{1}\) and Foret et al. in 1989.\(^{2}\) Although these publications addressed the CZE determination of some low-molecular-weight anionic species, a real breakthrough in the development of IPD in CZE was a consequence of the work of Jones and Jandik.\(^{3–8}\) These researchers were the first to report the analysis of 36 inorganic and organic anions in ca. 3.0 min using a chromate as the IPD electrolyte and tetradecyltrimethylammonium bromide (TTAB) to reverse the electroosmotic flow (Figure 12).\(^{8}\) Since that report, chromate has been the most widely used carrier
electrolyte for the analysis of inorganic anions (Table 3), for several important reasons. One is that chromate is a high-mobility anion that provides very symmetrical peak shapes for analysis of fast-moving inorganic solutes (e.g., bromide, chloride, nitrite, nitrate, sulfate, fluoride, and phosphate). In addition, this electrolyte possesses strong UV absorption over a broad (200–400 nm) range. The second reason is that detection using chromate is performed at 254 nm, which maximizes the largest possible number of anions to be detected universally, including those that are themselves UV-absorbing at low wavelengths. This is beneficial because most commercial CE instruments have a wide DR with low noise at 254 nm.

(continued overleaf)
Although the first recipe of chromate/TTAB electrolyte was very useful for IPD of many inorganic anions, this recipe has suffered from several problems. First, the electroosmotic flow modifier TTAB used in the chromate electrolyte was a bromide salt. Samples containing trace bromide levels induced a negative peak where bromide (generated from TTAB) normally migrates in the electropherogram. This negative peak not only decreased the bromide sensitivity but also caused problems with chloride integration. Second, the elution order of some inorganic anions (thiosulfate < bromide < chloride) was not very beneficial. A favorable elution order would be one in which chloride migrated first so that it could be used as a reference component. The benefit of this technique is easier peak identification based on the migration time ratio (migration time of analyte peak/migration time of the chloride peak). Additionally, referencing can also minimize drifts in the migration time due to changes in electroosmotic flow. Third, this recipe using the chromate electrolyte involved the electrolyte being prepared from the sodium salt and therefore unbuffered. It is well known that the use of an unbuffered electrolyte in CZE can cause electrolysis of water at the inlet and outlet vials.

To utilize better the benefits of chromate in IPD of inorganic anions, Mazzeo (36) has proposed reformulation of the chromate electrolyte. The author has reported the use of tetradecyltrimethylammonium hydroxide instead of TTAB. The conversion of TTAB to its hydroxide was accomplished by passing the former through an anion-exchange cartridge in the hydroxide form. The main problem with this procedure is the large excess of hydroxide ions introduced, resulting in a high-pH chromate. In such cases, it becomes necessary to reduce the pH with various organic acids (e.g. acetic acid or boric acid). However, a negative peak still appears in the electropherogram that corresponds to the migration time of the acid co-anion. Several reports have appeared describing the addition of low-mobility co-anionic buffers such as carbonate, borate, and CHES. Because of the low mobility of the aforementioned co-anionic buffers, a negative system peak is observed in the electropherogram but is well removed from the high-mobility inorganic anions. Nevertheless, the addition of

CHES, 2-(N-cyclohexylamino)ethanesulfonic acid; PDDPbCr, poly(1,1-dimethyl-3,5-dimethylenepiperidinium) chromate.
such buffering agents requires a careful pH optimization to prevent the interference of system peaks with analytes of interest. As suggested by Haddad, a more attractive alternative to buffer the chromate electrolyte is to use a buffering countercation such as Tris or diethanolamine in the chromate electrolyte.

Pyromellitic acid (PMA; or 1,2,4,5-benzenetetracarboxylic acid) is another suitable IPD reagent for the analysis of high-mobility inorganic anions. As a general observation, it can be said that currently chromate, PMA, and NTS are the three most suitable IPD reagents for the CZE analysis of high-mobility inorganic anions.

3.2 Indirect Photometric Detection of Inorganic Cations

As evidenced by recent reviews, CZE with IPD has been widely used in the analysis of inorganic cations (Table 4) in various samples. Unlike anion analysis, CZE separation of cations is easily obtained in the low pH range of 4–5 without modifying the capillary surface and without reversing the electroosmotic flow. Owing to small differences in the electrophoretic mobility of a metal cation, it has become quite common to include a neutral or anionic complexing agent in the IPD buffer to enhance cation selectivity. Short-chain mono-, di-, tri- and tetracarboxylic acids are the most popular complexing agents. Several authors have studied the use of tetracarboxylic acids for the separation of metal cations. In addition, to resolve the potassium and ammonium peaks from one another, 18-crown-6 is generally added to the IPD electrolyte.

The use of imidazole as carrier electrolyte with IPD was proposed initially by Beck and Engelhardt for both high-mobility alkali and alkaline earth metals, and has since been used by a number of authors. Although PMA offers higher molar absorptivity than chromate, the latter is still a preferred IPD reagent because of its excellent mobility match for the common inorganic anions. Mazzeo has also reported improved resolution and better peak shapes with shorter analysis time for inorganic anions using chromate instead of PMA.

Recently, naphthalenesulfonate reagents have been characterized by Shamsi and Danielson for IPD of a large number of inorganic anions. A comparison of NMS, NDS, and NTS revealed that NMS was the best electrolyte for aliphatic anionic surfactants, whereas NDS and NTS caused more efficient separation of inorganic anions (Figures 3 and 4). NDS, in particular, was found to be applicable for efficient CZE separation for a much wider analyte range. For example, NDS electrolyte provided successful IPD of all three classes of anions, namely inorganic anions, organic acids, and aliphatic anionic surfactants.

Several other IPD reagents, including phthalate, trimellitate, o-benzylbenzoic acid, sulfobenzoic acid, and 1-nitroso-2-naphthol-3,6-disulfonate have also been examined. However, these reagents provide sensitive IPD of only a few inorganic anions. As a general observation, it can be said that currently chromate, PMA, and NTS are the three most suitable IPD reagents for the CZE analysis of high-mobility inorganic anions.

ELECTRONIC ABSORPTION AND LUMINESCENCE

metals. The authors noted that monoprotic acids (acetate, lactate, α-HIBA) showed the weakest complexation with divalent cationic solute, whereas the triprotic acid citrate showed the strongest. Yang and Francois have also investigated imidazole as an IPD electrolyte but used 18-crown-6 as the complexing agent. Both groups of researchers obtained maximum resolution of ammonium and potassium cations using this complexant. Quang and Khaledi optimized the concentration of complexant α-HIBA using a simple univariate approach. The researchers developed a migration model to predict the elution time of 14 metal cations.

as a function of pH and α-HIBA concentrations. The computer simulation predicted the optimal conditions to be 12 mM α-HIBA and pH 3.5. Again, 6 mM imidazole was used at the optimal pH and complexant concentration that provided a fast separation of metal cations in <4 min.

Monofunctional aromatic bases such as 4-methylbenzylamine, \(^{70,72}\) \(N,N\)-dimethylbenzylamine, \(^{73}\) benzylamine, and pyridine \(^{73–75}\) have been shown to provide good CZE separation of mono-, di-, and trivalent cations. Weston et al. \(^{70,71}\) showed that the simultaneous CZE separation of alkali, alkaline earth, and transition metals, as well as lanthanides, is possible using 5 mM MBA electrolyte and 6.5 mM α-HIBA at pH 4.4. Using this IPD electrolyte, they reported ca. 100 µg L⁻¹ detection limits for 28 metals. The peak capacity for cation separations in CZE is not as high as for anions. However, indications of improved peak capacity have been reported by Shi and Fritz. \(^{72}\) Using 8 mM MBA, 15 mM lactic acid, and 5% methanol at a pH of 4.25, resolution of 27 metal cations
in a single run was achieved in only 6 min (Figure 14). In a separate paper, Shi and Fritz were able to resolve potassium and ammonium ions when crown ether was added to the same IPD reagent. Further addition of crown ether caused Sr$^{2+}$ to move ahead of Ba$^{2+}$ and allowed the resolution of these ions. The authors also suggested the use of 8% methanol with low applied voltage and low injection size as a possible solution to the problem of determining a trace amount of metal ions (e.g., 1 ppm Ca$^{2+}$, Mg$^{2+}$, Sr$^{2+}$, or Ba$^{2+}$) in the presence of a very high concentration of another metal ion (e.g., 1000 ppm of Na$^+$. On the other hand, Yang et al. have advocated the use of an imidazole–sulfuric acid buffer system rather than MBA as a means of improving the peak shapes of sodium when injected at high concentration. Chen and Cassidy optimized the CZE separation of metal cations in terms of the nature of the IPD reagent, the concentration of the complexant, the pH, and the surfactant type and concentration. Optimal conditions were 6 mM N,N-dimethylbenzylamine, 4.2 mM HIBA, and 0.2 mM Triton X-100 at pH 5.0 (adjusted with acetic acid). Under these conditions CZE separations of 26 metal cations was attained in <11 min. The detection limits were in the range 0.6–1 µg mL$^{-1}$ for lanthanide, transition and alkaline earth metal ions, and in the range 0.1–0.8 µg mL$^{-1}$ for alkali metal ions.

Several other IPD reagents have been described for CZE separation of inorganic cations. These include ephedrine, benzimidazole, copper(II), diphenylphosphonium hydroxide, 2-AP and guanidine·HCl. In general, they have all shown good CZE separation of metal cations but not exceptionally high peak capacity. Of the various cationic IPD electrolytes described in this section, imidazole and MBA seem to provide the best overall performance in terms of selectivity, resolution, and peak capacity of inorganic cations. However, more work is still needed to improve the peak capacity for cation separations up to the level achieved for IPD of anions.

### 3.3 Indirect Photometric Detection of Short-chain Organic Acids and Amines

IPD is normally required for the analysis of most short-chain polar anions of organic acids (e.g. oxalate, malonate, formate, acetate, and propionate). This is because many of these organic acids do not fluoresce and have negligible absorbance at useful wavelengths in the

CTAB, cetyltrimethylammonium bromide; MTAB, myristoyltrimethylammonium bromide.
UV region. Various IPD electrolytes have been used in the analysis of organic acids. Again, the choice of the IPD reagent is governed by the need to obtain symmetrical peak shapes by closely matching their charge and electrophoretic mobility with those of the organic acids. Wu et al. evaluated chromate, pyromellitate, trimellitate, phthalate, terphthalate, and benzoate as IPD reagents for the determination of 10 organic acids. (61) Trimellitate was found to be the most suitable reagent because it provided the closest mobility match to the analyte with the highest molar absorptivity. In addition, various IPD reagents such as naphthalenedicarboxylic acid (NDC), (48,84,85) trimellitate (47,60–62), phthalate, (20,39,86–88) NDS and NTS (35) all have suitable molar absorptivity and mobility matches that enable them to be of use for IPD of organic acids.

IPD has proved to be reliable for the quantitation of organic acids in real samples (e.g. urine, (86) beverages, (89) Bayer liquor (80)). However, the IPD method requires appropriate capillary conditioning procedures. For example, Soga and Ross found that when phthalate or trimellitate was employed as IPD reagent for the determination of organic acids, citrate and oxalate were not observed at concentrations below 50 mg L\(^{-1}\). (89) Additionally, the S/N of malate deteriorated. The authors concluded that the decrease in S/N was due to adsorption of these organic acids onto the capillary wall. A procedure for rinsing the capillary with phosphoric acid before each run was proposed. However, a large phosphate peak appeared, which masked the analyte peaks. The use of a pyridinium chloride electrolyte was proposed as an alternative. This IPD electrolyte has the potential to complex with the metal impurities on the capillary wall, hence reducing the adsorption of the organic acids.

Table 5 lists the range of organic acids that have been analyzed employing CZE with IPD. Generally, the determinations of organic acids using the IPD method have been successful. Figure 15 shows an electropherogram obtained for the analysis of 18 organic acids in <7 min. (91) Although sensitivity in CZE is undoubtedly a major limitation, many IPD reagents (e.g. NDC, NDS) can be employed to lower the LOD. (84,85) The utility of CZE for the simultaneous measurement of short-chain organic acids and inorganic anions can be appreciated by considering the separation power and time as benefits of this technique. It should be noted that neither ion-exchange high-performance liquid chromatography (HPLC) nor ion-exclusion HPLC provides a complete separation of these compounds in IPD mode.

Even though there are a great number of samples that contain organic bases such as biogenic polyamines, food samples are the most common applications. Problems are often encountered with conductometric cation-exchange HPLC for the analysis of short-chain polyamines because these polyprotonated species are highly charged in typical acidic eluents. Unless the eluent pH is high, the elution of polyamines using cation-exchange chromatography is problematic. For these reasons, CZE with IPD is attractive because it affords a simple means of facilitating both separation and detection. The potential of CZE with IPD for the determination of biogenic amines has been recognized by several authors. One of the early reports in the IPD of amines is by Beck and Engelhardt. (25) Simultaneous separation of metal ions, amines, and amino alcohols was obtained using 5 mM imidazole as the IPD electrolyte at a pH of 4.5. A complete CZE separation was achieved in ca. 4 min, with a \(C_{LOD}\) of around 0.4 ppm. Some polyamines (e.g. putrescine, spermine, and spermidine) along with inorganic cations and basic amino acids in tumor cells were determined simultaneously in <10 min by Ma et al. (92) The system employed quinine sulfate as IPD reagent at a pH of 5.9. Mass detection limits attained by this method were in the femtomole range with a linear detection response of two orders of magnitude. Extensive optimizations by Arce et al. (93) have shown that cupric sulfate is an ideal IPD electrolyte for the detection of biogenic amines. A rapid separation of 21 amines using this optimized electrolyte system is shown in Figure 16. A typical detection limit attained by this method for biogenic amines was 0.05 ppm. Although the linear concentration range (0.05–10 ppm) was rather narrow, the recoveries (90–110%) obtained for the representative amines were reasonable.
Figure 16 Electropherogram of a standard mixture of amines: (1) ammonia; (2) methylamine; (3) L-3-diaminopropane; (4) putrescine; (5) histamine; (6) cadaverine; (7) agmatine; (8) ethylamine; (9) ethanolamine; (10) spermidine; (11) propylamine and morpholine; (12) isopropylamine; (13) diethylamine; (14) butylamine; (15) spermine and isobutylamine; (16) amylamine and isoamylamine; (17) 1-methylbutylamine; (18) hexylamine; (19) phenylethylamine; (20) heptylamine; (21) tyramine. The electrolyte comprised 4 mM cupric sulfate, 4 mM formic acid and 4 mM 18-crown-6 at pH 3.0. The separation was performed at 10 kV. (Reproduced with permission from Arce et al. 3.4 Indirect Photometric Detection of Long-chain Fatty Acids

Long-chain free fatty acids (FFAs) are an important class of naturally occurring compounds that can be found in living cells. Because these compounds contain an acidic hydrogen, they predominantly exist as anions in basic solution. Considering the differences in mass-to-charge ratios, both saturated and unsaturated FFAs can be separated by CZE. However, saturated FFAs exhibit only a weak absorption band in the region of 200 nm. Therefore, CZE with direct UV detection is problematic and leads to limited sensitivity. Currently, CZE with IPD is of considerable interest for the determination of long-chain saturated FFAs (Table 6).\textsuperscript{145,94–98}

Probably the first attempt to separate long-chain FFAs in CZE with IPD was reported in 1994 by Gutnikow et al.\textsuperscript{195} Both normal and reversed electroosmotic flow in CZE was developed using TNBSA as the IPD reagent. Although, a rapid separation in <7 min of FFAs up to C\textsubscript{10} was achieved in reversed electroosmotic flow mode using 30% acetone, peak capacity was much higher in the normal mode. For example, in the normal mode, analysis of C\textsubscript{3}–C\textsubscript{18} organic acids was feasible in <20 min using 60% acetonitrile. Despite the use of low-mobility TNBSA as the IPD reagent, the electropherogram showed asymmetric peaks for C\textsubscript{14}–C\textsubscript{18} FFAs. Buchberger et al.\textsuperscript{195} resolved both short- and long-chain FFAs in a reversed CZE mode with reversed polarity. The solubility parameters and adsorption of FFAs on capillary walls were overcome with the use of 70% ethyleneglycol monomethyl ether and trimethylammonium propanesulfonate in the IPD buffer. The FFAs in butter were profiled; however, one of the limitations of this method was its inability to resolve isomers of FFAs. Nevertheless, the simplicity of the sample preparation could be beneficial for routine analysis.

Roldan-Assad and Gariel developed a CZE method for the determination of C\textsubscript{2}–C\textsubscript{14} linear FFAs.\textsuperscript{145} Because long-chain FFAs (≥C\textsubscript{14}) have limited water solubility and their tendency to form micelles decreases the separation selectivity between successive homologs, IPD electrolytes containing cyclodextrins and 60% methanol were used to enhance both solubility and selectivity. However, this occurred at the expense of a slightly longer analysis time (>16 min). The C\textsubscript{LOD} values of FFAs were approximately 0.2 ppm (1 × 10\textsuperscript{-6} mol L\textsuperscript{-1}) and the detection linearity was extended over three orders of magnitude (10\textsuperscript{-6}–10\textsuperscript{-3} mol L\textsuperscript{-1}). Collet and Gariel\textsuperscript{196} later studied the effect of cyclodextrin type and concentration for the separation and indirect detection of saturated and unsaturated FFAs ranging between C\textsubscript{14} and C\textsubscript{18}. The authors concluded that the CZE method developed using cyclodextrin was not suitable for the separation and IPD of very-long-chain (C\textsubscript{19}–C\textsubscript{31}) FFAs.

Drange et al.\textsuperscript{197} first used nonaqueous electrolyte for CZE separation of very-long-chain FFAs. The authors showed that the separation of C\textsubscript{12}–C\textsubscript{20} acids could be accomplished conveniently in 15 min using ANTs in N-methylformamide and dioxane. Recently, Haddadian et al. investigated the CZE separation of long-chain saturated C\textsubscript{12}–C\textsubscript{31} FFAs differing by only one carbon atom.\textsuperscript{198} Figure 17 shows an impressive separation of C\textsubscript{12}–C\textsubscript{31} FFAs under the optimum conditions using AMP as IPD reagent. Because AMP was found to be soluble in aqueous and partially aqueous, as well as nonaqueous media, it appears to be an excellent IPD electrolyte for the separation and IPD of complicated mixtures of both saturated and unsaturated FFA isomers (Figure 18).

3.5 Indirect Photometric Detection of Phosphates and Phosphonates

CZE with IPD has recently emerged as a valid alternative to the more traditional postcolumn IC method for the determination of both phosphates and phosphonates (Table 7).\textsuperscript{24,99–101} Advantages of CZE over IC for these

compounds are large peak capacity, short analysis time, better efficiency, and minimal sample and reagent consumption. Despite the fact that Jones and Jandik demonstrated chromate to be the best IPD electrolyte for the separation of 30 inorganic anions and short-chain organic acids in ca. 3.0 min, the utility of chromate for the separation of relatively high-molecular-weight and less-mobile phosphates and phosphonates is poor. For example, peak tailing and poor migration time and area reproducibility of orthophosphate were observed by a number of researchers using a chromate electrolyte. Theoretical considerations suggest that reagents that can be useful for indirect detection of phosphate and phosphonate derivatives should have medium to low mobility, a relatively high $\epsilon$, and a favorable DR.

Linear polymers of phosphoric acid, all of which contain phosphorus–oxygen linkages, are termed linear $P_n$.

The first report on CZE/IPD applied to the separation of $P_1–P_3$ phosphates using a phthalate electrolyte at a pH of 4.0 was described by Stover et al. 99 However, the system was not fully optimized and the method was reported to have marginal baseline stability and

CMP, cytidine 5′-monophosphate; GMP, guanosine 5′-monophosphate; UMP, uridine 5′-monophosphate; ATP, adenosine 5′-triphosphate; PPA, phenylphosphonic acid; AMPA, aminomethylphosphonic acid; DTAB, dodecyltrimethylammonium bromide; HMOH, hexamethonium hydroxide.
reproducibility. When the calibration plots of normalized peak area vs. concentration were drawn for \( P_1, P_2 \) and \( P_3 \) phosphates, approximately the same slopes but different intercepts were observed. For example, \( P_2 \) and \( P_3 \) phosphates provided nearly equal slope values but large negative intercepts. The authors concluded that the reason for the low detection sensitivity of \( P_2 \) and \( P_3 \) phosphates might include interaction with the surfactant (e.g., dodecyltrimethylammonium bromide used as a modifier for reverse electroosmotic flow) and/or on-line hydrolysis. In an attempt to improve the reproducibility, Shamsi and Danielson first evaluated the use of ribonucleotides, namely AMP, CMP, GMP, and UMP, as IPD electrolytes for the simultaneous separation of 12 \( P_n \) and RP\(_n\) in <30 min. These reagents contain a phosphate group in their structure, thus preventing any irreversible binding of \( P_n \) and RP\(_n\) with the silanol groups. Even though all of the ribonucleotides were able to separate a mixture of \( P_n \) and RP\(_n\) with reasonable selectivity, AMP was found to be the best electrolyte because of its high \( \epsilon \), large DR and favorable TR required for sensitive IPD. The quality of separation of some \( P_n \) (particularly \( P_3 \) and \( P_4 \) phosphates) was dramatically improved by incorporating \( Mg^{2+} \) in the running buffer with positive polarity. As a result, the reproducibility of migration times is 0.5–1.0% relative standard deviation (RSD). One practical application reported was the determination of phosphates and phosphonates in soap and various brands of toothpaste. Later Wang and Li \(^{100, 105}\) reported the use of ATP at pH 3.5 for the CZE separation and IPD of cyclic \( P_3 \) phosphate, monofluorophosphate and \( P_1-P_3 \) phosphates. Although the value of DR for ATP was \( 2.8 \times 10^5 \), which is much greater than that obtained by Shamsi et al.\(^{24}\) using AMP (DR = 612), the detection limits for \( P_n \) were not improved. This implies that the greater DR obtained for ATP was compensated by a loss in TR.

The CZE separation of \( P_n \) with chain length \( \geq 4 \) is more challenging because of their similar electrophoretic mobility. Again, Stover first explored the buffer containing PMA with hexamethonium hydroxide for high-efficiency separation and IPD of \( P_n \).\(^{106}\) Glassy sodium \( P_n \) with average chain lengths of 5–44 were analyzed in less than 20 min. Stover thought that the cationic electroosmotic flow modifier hexamethonium would ion-pair with the anionic \( P_n \) leading to improved CZE separation. After this success in the CZE mode, Wang and Li recently reported the separation of higher-chain-length \( P_n \) using capillary gel electrophoresis (CGE).\(^{1107}\) Presumably, the sieving effect of the gel provided good resolution of \( P_n \). Wang and Li used the same PMA electrolyte as Stover used,\(^{106}\) but without the use of hexamethonium hydroxide. The migration order of linear \( P_n \) was found to be based on charge-to-size ratios. For example, migration time first increased from \( P_2 \) to \( P_4 \) phosphate, but \( P_1 \) phosphate eluted later, followed by all linear \( P_n \). The authors reported that quantitative analysis of \( P_n \) was difficult due to the bias generated by the electrokinetic injection. Currently, systematic approaches to the design of a novel buffer system and IPD reagents that offer enhanced selectivity and sensitivity for long-chain \( P_n \) are still being developed. As yet, they are not at the point where buffer recipes can be employed conveniently for routine separations of these long-chain \( P_n \) in CZE or CGE mode. However, there is no doubt that CE methods for \( P_n \) will substitute for IC in specific applications.

IPD of inositol phosphates after their separation by CZE was studied by Henshall et al.\(^{39}\) at low pH using a dichromate and phthalate electrolyte. Although the use of chromate provided separation of all four inositol (mono-, bis-, tris-, and hexakis-) phosphates in less than 10 min, the separation window was rather narrow (0.7 min) and therefore shifts in the migration time resulted in peak misidentification. On the other hand, phthalate when buffered at pH 5.9 provided acceptable results with excellent sensitivity for the inositol mono- and bis-phosphate, but this electrolyte does not seem to be useful for the separation of all four inositol phosphates in a single run. The CZE/IPD methodology for the determination of six inositol phosphates in fermentation broth was also investigated by Buscher et al.\(^{108}\) Using 1-naphthol-3,6-disulfonic acid (NDSA) as the IPD reagent, the authors reported the baseline resolution of inositol mono-, bis-, tris-, and tetrakisphosphates, whereas inositol pentakis- and hexakisphosphates remain unresolved.
Phosphorus-containing surfactants, namely mono- and diesters of aliphatic organophosphates, are used in a wide variety of applications. The determination of these compounds is of relevance not only in the detergent industry, owing to their surface-active property, but also in medicinal research, as well as the nuclear and fuel processing industry. Recently, Shamsi et al. developed a CZE/IPD method for analysis of alkyl phosphates. An example electropherogram showed that the separation of 10 C1–C6 mono- and diesters of phosphate is possible in ca. 11 min using AMP electrolyte at pH 7.2 (Figure 19a). Although the resolutions of some phosphate esters were improved at a higher pH value of 10.5, the S/N decreased significantly under such conditions (Figure 19b). Hence, a pH of 7.2 was recommended for the analysis of these aliphatic organophosphates.

Alkylphosphonic acids have considerable agricultural and biological importance due to their biocidal potency and their presence at trace levels in various antibacterial (fosfomycin) or antiviral (foscarnet) formulations. Pianetti et al. have utilized PPA at 200 nm for the IPD of C1–C4 phosphonates in less than 10 min. The authors reported that an increase in borate concentration resulted in a better S/N. In contrast, S/N decreased with increasing concentration of PPA. The calibration plots based on peak height for C1–C4 phosphonates showed a linear range of 5–50 µg mL⁻¹ with an RSD of less than 3.8%. Moreover, the mass LOD of alkylphosphonic acids was

Figure 19 Effect of pH on the separation of a standard mixture of 10 mono- and diesters of phosphates: (a) AMP at pH 7.2; (b) AMP at pH 10.5. All electrolytes contained 100 mM H3BO3. Peak identification: 100 mg mL⁻¹ each of (1) diethylhexylphosphate; (2) dibutylphosphate; (3) diisopropylphosphate; (4) diethylphosphate; (5) monoethylhexylphosphate; (6) monobutylphosphate; (7) monoisopropylphosphate; (8) monoethylphosphate; (9) monomethylphosphate; (10) dimethyolphosphate. Vacuum injection for 2 s; +30 kV applied for separation; current is 8 µA and 70 µA at pH 7.2 and 10.5, respectively; IPD at 259 nm. (Reproduced with permission from Shamsi and Danielson.)

Inositol trisphosphate was the only compound that provided a closer mobility match to NDSA, resulting in symmetrical peak shape. Hence, this approach was extended further by the same authors for the analysis of inositol trisphosphate in plasma.

Figure 20 Separation of alkylphosphonic acids. Experimental conditions: buffer is 200 mM borate and 10 mM PPA; 75 µm (i.d.) × 56 cm fused-silica capillary; peaks detected by indirect UV detection at 210 nm; injection for 6 s at 50 mbar; temperature = 40 °C; 0.35 mM didodecyldimethylammonium hydroxide and 0.03 wt.% Triton X-100, pH 4.0; voltage = 30 kV (negative polarity). Anions: (1) O-(2-ethylhexyl)methylphosphonic acid; (2) methylphosphonate; (3) ethylmethylphosphonate; (4) isopropylmethylphosphonate; (5) isobutylmethylphosphonate; (6) O-isopropylethylphosphonic acid; (7) cyclohexylmethylphosphonate; (8) pinacolylmethylphosphonate. (Reproduced with permission from Nassar et al. Copyright 1998 American Chemical Society.)
ca. 0.21 pmol. Another application of phosphonate compounds is glyphosate, with its major metabolite AMPA. Shamsi et al.\cite{24} also developed a normal-polarity CE method using AMP electrolyte for quantitation of these two analytes in a commercial herbicide solution. Likewise, Cikalo et al.\cite{111} also reported the analysis of glyphosate and AMPA using CZE/IPD. However, these employed a reverse-polarity CE with phthalate as the IPD reagent. Although the use of electrokinetic injection provided improved detection limits, the application of the method to wheat samples was unsuccessful. This is because of the high conductivity of the extracted sample, which prevented injection in the electrokinetic mode. Very recently, Nassar et al.\cite{101,112} in a series of two publications used PPA as the IPD electrolyte for the separation and indirect detection of short-chain alkylyphosphonates (also known as chemical warfare agent degradation products). The phosphonates studied included methylphosphonic acid, monoisopropylphosphonic acid, and the monoalkyl esters of methylphosphonic acid. Using a mixed surfactant system (0.35 mM didodecyltrimethyl ammonium hydroxide, 0.03 wt.% Triton X-100) to reverse the electroosmotic flow, and PPA as the IPD electrolyte, complete separation of phosphonates was accomplished in less than

3 min (Figure 20). The authors found this electrolyte system to be stable for at least three months. The detection limit reported was about 100 µg L\(^{-1}\). Moreover, the method was applied to the aqueous leachates of soil, wipes of surfaces, and vegetation samples known to have been exposed to nerve agents. Nassar et al. in the same laboratory expanded this work with quantitative analysis of chemical warfare degradation products in reaction masses. They found that the CZE/IPD methodology can provide a limit of quantitation of 500 µg L\(^{-1}\) and an LOD of 100 µg L\(^{-1}\) for both isopropylmethaphosphonic acid and pinacolylmethylphosphonic acid, with a linear response over the range 0.5–100 µg L\(^{-1}\).

### 3.6 Indirect Photometric Detection of Aliphatic Anionic and Cationic Surfactants

Aliphatic anionic and cationic surfactants are important additives that are widely used as cleaning agents, dispersants, emulsifiers, solubilizers, and stabilizers. Structurally, many of these compounds consist of an aliphatic hydrocarbon tail with a polar head group and nonchromophoric substituent. Recent reports on the separation of nonchromophoric anionic surfactants indicate that CE is a complementary technique to reversed-phase IC with respect to retention order. IC with respect to retention order.

In the analysis of anionic and cationic surfactants (Table 8), a medium- to low-mobility IPD co-ion must be chosen. For the determination of nonchromophoric anionic surfactants such as alkyl sulfates, alkane sulfonates, alkylether sulfates, and alkylsulfonic succinates, several IPD reagents have been explored. Numerous IPD electrolytes used for anionic surfactants include veronal, NMS, salicylate, dihydroxybenzoic acid, PTS, dinitrobenzoic acid, AMP, and octyl- and dodecylbenzene sulfonate. In contrast, there are only a few reports on the CZE separation of non-UV-active cationic surfactants. The strong adsorption of these substances at the inner wall of a fused-silica capillary is clearly a matter of concern. However, recent reports have indicated that a large volume of organic solvents can help to overcome this problem. By far the more prominent IPD reagents for cationic surfactants include benzylidimethyldecylammonium, benzylationamine, ephedrine, benzytrimethylammonium, and tetrazolium violet.

The separation of complex mixtures of alkyl sulfates and alkane sulfonates of identical chain length is a challenging problem in CZE because of their very similar electrophoretic mobilities. Figure 21 is a typical electropherogram obtained using the best anionic IPD reagent, such as NMS with 50% methanol, to enable the baseline separation of C\(_6\)–C\(_{18}\) SO\(_3\)\(^-\)/SO\(_3\)\(^-\) pairs in 30 min. A similar electropherogram but with lower sensitivity could be generated with PTS as the IPD reagent.

### 3.7 Indirect Photometric Detection of Carbohydrates

The determination of carbohydrates (Table 9) provides a unique challenge to a separation chemist. This is because most carbohydrates do not possess strong chromophores in their structure and are therefore not accessible to direct detection in the UV. For these reasons, carbohydrates are generally derivatized with a suitable chromophore such as 2-AP or p-aminobenzoic acid for direct UV detection, or by indirect detection using a suitable light-absorbing reagent. It is well known that carbohydrates are very weak acids; therefore very-high-pH eluents have been used for their separation via anion-exchange chromatography. A number of researchers have also utilized high-pH (pH ~ 12) electrolytes for the CZE separation of carbohydrates in the IPD mode.

Vorndran et al. have shown that sorbic acid is a very useful IPD reagent for several important reasons. First, sorbic acid has high molar absorptivity (\(\epsilon = 27,800\) at 256 nm). Second, it carries a single charge, which ensures a favorable TR value. Third, it does not interact with the

NAA, 1-naphthylacetic acid.

Capillary surface or with the analyte. Fourth, it has an effective mobility that matches well with the mobilities of the ionized sugars. Vorndran et al.\textsuperscript{23} found increased resolution of carbohydrates as the pH was increased, but a drastic drop in IPD sensitivity was observed as the pH increased past 12.2. They postulated that the decrease in IPD sensitivity is probably due to the displacement of nonabsorbing hydroxide ion, rather than sorbate ions, by the analytes. In addition they determined the best compromise pH for sensitive detection of carbohydrates to be 12.1. At this pH, $C_{LOD}$ was about 0.5 mM. In a similar study, Vorndran et al.\textsuperscript{51} investigated the effect of sorbate concentration on the IPD signal. The researchers reported that a lower concentration of sorbate adversely affects the TR value due to competition with hydroxide ion. On the other hand, at high sorbate concentrations S/N again deteriorates because less light is able to reach the photodiode. Likewise, Klockow et al.\textsuperscript{126} used sorbate as an IPD reagent for the determination of carbohydrates in a variety of fruit juices. Again, the optimum CZE conditions were found with a buffer of pH 12.2–12.3.
Lee and Lin\textsuperscript{127} have evaluated the potential of six IPD reagents for the determination of carbohydrates: NAA, 2-naphthalenesulfonic acid, 1,3-dihydroxynaphthalene, phenylacetic acid, p-cresol, and sorbic acid. They noted that NAA is the best IPD reagent for CZE separation of eight sugars (sucrose, lactose, maltose, glucose, rhamnose, ribose, gluconic acid) (Figure 22). In addition, NAA also provided a three- to sixfold increase in separation efficiency and about a fivefold improvement in the detection limit (0.1 mM) when compared with sorbate. Lu and Westerlund\textsuperscript{128} reported the utility of tryptophan as another IPD electrolyte for the determination of carbohydrates, which provided at least a twofold improvement in detection limits over sorbate.

CZE/IPD of underivatized carbohydrate based on sorbate or riboflavin electrolytes has also been exploited by several researchers.\textsuperscript{129,130} Xu et al.\textsuperscript{129} have used narrow (25 µm) capillaries and low voltages at high pH to improve the \( C_{\text{LOD}} \) of underivatized sugars. After optimization of the CZE conditions, the pH range for the separation was extended to 13. The \( C_{\text{LOD}} \) of sugars at this high pH was of the order of 0.05–1.0 mM. The developed method was applied to the analysis of culture medium samples. Liu et al.\textsuperscript{130} reported a three- to fivefold improvement in separation efficiency with a stable baseline using diethylamine as an electrolyte additive, when compared to sodium hydroxide, at a pH as high as 12.6. It was hypothesized that low-conductivity diethylamine forms ion-pairs with anionic carbohydrates, and also suppresses electroosmotic flow by masking the silanol group at the capillary surface. The authors also reported improved separation of di- and trisaccharides with a borate buffer at pH 9.5, in place of sodium hydroxide or diethylamine, keeping the type of IPD reagent (sorbate, riboflavin) constant for both variations.

CZE/IPD for the qualitative and quantitative analysis of low-molecular-weight glycosaminoglycans (heparins) was reported by Damm et al.\textsuperscript{131} Although heparin fragments are also amenable to direct UV detection at 232 or 200 nm, the use of 5-sulfosalicylic acid or 1,2,4-tricarboxybenzoic acid in IPD mode provides an order of magnitude higher sensitivity than direct UV detection.

Cyclodextrins belong to another class of nonchroomophoric carbohydrates that can be resolved by CZE provided that the IPD reagent binds selectively with the central hydrophobic core of the cyclodextrin molecules. Nardi et al.\textsuperscript{132} separated \( \alpha, \beta, \gamma \), and \( \delta \)-cyclodextrins at a pH of 6.2 using 30 mM benzoic acid as the IPD reagent. The authors demonstrated that formation of an inclusion complex of benzoate with the cyclodextrins can be beneficial for quantitative analysis of the latter in drug formulation. Various charged and uncharged cyclodextrins have also been shown to be detected in the IPD mode after their CZE separation using a range of aromatic anions.\textsuperscript{133–135} However, it is postulated that the absorbance difference caused by cyclodextrins is probably due to displacement of the IPD reagent in the sample zone rather than a specific absorption change caused by inclusion complex formation.

Very recently a mixture of six different phosphorylated sugars and other organophosphorus compounds of biochemical interest (e.g. glucose-6-phosphate, fructose-6-phosphate, fructose-1,6-biphosphate, dihydroxyacetone phosphate, glyceraldehyde-3-phosphate, 2-phosphoglycerate) found in the glycolytic pathway were resolved under CZE/IPD conditions by Schaeper et al.\textsuperscript{136} They found optimum analysis with 5 mM AMP and 100 mM boric acid at a pH of 7.2. Although the authors reported successful separation of five monophosphorylated sugars using the same conditions as for the glycolytic pathway, the separation of bisphosphorylated sugars could not be achieved unless magnesium was added to the AMP buffer. On the other hand, when NDS was used as the IPD electrolyte, the separation of biphosphorylated sugars was

---

DMAB, 4-(N,N'-dimethylamino)benzoate.

possible without the addition of magnesium. With a 5-s vacuum injection into the capillary the authors reported a detection limit of 0.5–1 ppm (S/N = 3).

### 3.8 Indirect Photometric Detection of Amino Acids and Phospholipids

A number of publications have described the successful CZE separation of underivatized amino acids with IPD (Table 10).\(^{[137–141]}\) Lee et al.\(^{[137]}\) have evaluated nine IPD reagents for the analysis of a mixture of 20 common amino acids. The IPD reagents evaluated were sorbate, benzoate, phthalate, nicotinate, salicylate, \( p \)-aminosalicylate (PAS), \( p \)-aminobenzoate, DMAB, and 7-amino-4-hydroxy-2-napthalenesulfonate (AHNS). These authors found that both type and concentration of the IPD reagents influence the separation behavior and detectability of amino acids. Two IPD reagents (PAS and DMAB) were recommended for the routine analysis of amino acids because they have effective mobilities that match closely the mobilities of most amino acids at high pH. For example, Figure 23 shows that the resolution of 17–19 amino acids can be achieved in 35 and 50 min, respectively, using PAS or DMAB, respectively, at pH 11 with normal polarity.\(^{[138]}\) This was possible upon addition of 20 mM \( \alpha \)-cyclodextrin to PAS or DMAB at pH 11.0 (Figure 23). In a systematic approach to separate amino acids, Chen et al.\(^{[139]}\) used CZE with IPD for the analysis of amino acids in urine. Resolution was achieved by adjusting pH, buffer concentration, and
Figure 23 Electropherogram of 20 common amino acids in 10 mM PAS (a) and 10 mM DMAB (b) in the presence of 20 mM α-cyclodextrin (Sigma) at pH 11.0. Concentration of amino acids, 0.5 mM each. Peak identification: K = Lys, P = Pro, L = Leu, I = Ile (not resolved), W = Trp, F = Phe, M = Met, H = His, V = Val, Q = Gln, T = Thr, N = Asn, A = Ala, S = Ser, G = Gly, Y = Tyr, C = Cys, E = Glu, D = Asp. the type of IPD reagent (benzoate, salicylate). Similarly Hong et al.140 have also optimized the separation of amino acids with IPD. They indicated that the choice of IPD reagent is critical for the efficiency of separation in CZE. Using the optimized conditions, baseline separation of 13 amino acids was reported. One recent report142 demonstrated CZE separation of phosphoamino acids using AMP as the IPD reagent. Baseline resolution of three phosphoamino acids (phosphoserine, phosphothreonine, phosphotyrosine) without co-migration of two native amino acids (glutamic acid, aspartic acid) was accomplished in less than 20 min with detection limits in the micromolar range. An interesting application of the IPD method for the determination of phosphoserine in the protein phosvitin after acid hydrolysis was also described in this report.142

Currently, there are only a few reports on the CZE separation of anionic phospholipids (Table 10).143-145 In the separation of these very hydrophobic anions, MEKC with direct UV detection is preferred. However, the C_{LOD} using direct detection is rather poor even at a wavelength of 200 nm. CZE/IPD was recently reported by Haddadian et al.145 for the determination of C_{12}-C_{18} phosphatidic acids, phosphatidylinerine, phosphatidylinositol, phosphatidylglycerol, and cardiolipin, giving LOD values in the low-ppm range for these anionic phospholipids. The
authors demonstrated the versatility of AMP by utilizing it as the IPD reagent for the analysis of phospholipids in soybean and brain extracts.

4 SIMULTANEOUS SEPARATION AND INDIRECT DETECTION OF CATIONS AND ANIONS

The potential of CZE for the simultaneous separation of cations and anions with IPD holds particular promise for ion analysis for several important reasons. First, combined separation and detection is very convenient compared to individual separations because more information about sample cations and anions as well as the chemical processes can be obtained in a single run. Second, it is obvious that this approach is cost-effective with less work and a shorter analysis time. Although, at the present time, only few research groups worldwide are actively engaged in the development of these analytical methods, the method has the potential to broaden the scope of CZE applications.

Despite the merits discussed above, simultaneous separation and IPD of cations and anions is problematic in CZE because when the voltage is applied cations and anions tend to migrate inherently toward their respective electrodes. Because a detector is generally located on one side of the capillary, proper control of both migration direction and migration velocity is essential, so that the two classes of ions of opposite charges can move in the same direction. There are four major approaches that have been developed to cope with the aforementioned problem. The first approach utilizes Ce$^{3+}$ and $p$-hydroxybenzoate counterions for IFD of some small inorganic cations and chloroanions respectively. However, dual detectors (one at each end of the capillary) are required, making this approach difficult to adopt in a commercial CE system. The second approach, first reported and applied in IPD by Shamsi and Danielson$^{(113)}$ and later by Xiong and Li$^{(147,148)}$ is based on the principle that if the velocity of electroosmotic flow is high enough, then both cations and anions can be determined in one run provided that they have a suitable mobility match with their respective indirect photometric co-ions. The third approach is described by Kuban et al.$^{(149)}$ in which the detection window is placed approximately in the center of the capillary and the sample is injected from both ends of the capillary. Finally, the last approach reported recently$^{(150)}$ describes the metal cations being transformed into anionic chelates after their complexation with ethylenediaminetetraacetic acid. Hence, cations are separated together with anions under the co-electroosmotic flow conditions in CZE. Unfortunately, with this approach alkali metals and ammonium cations cannot be determined because they do not form stable complexes with ethylenediaminetetraacetic acid.

4.1 Selection of Suitable Cationic and Anionic Indirect Photometric Detection Reagents

In evaluating light-absorbing co-cations and co-anions for simultaneous separation and IPD of the nonchromophoric cations and anionic analytes, several factors should be considered:$^{(113,147,148)}$

1. A two-component IPD solution must be chromophoric with high $e$ and DR.
2. The IPD reagent must provide a suitable mobility match, i.e. small $\Delta T$ value ($\Delta T =$ migration time of the IPD reagent minus the migration time of analyte ion).
3. IPD reagents should preferably be strong bases or acids to ensure that high fractions of both are ionized. For example, cationic IPD reagents should have a high $pK_a$ value so that they can be displaced effectively by the nonchromophoric cationic analytes even at higher pH. In addition, anionic IPD reagents should be strong acids so that they could not only adjust the solution pH but also provide charge displacement with good sensitivity at low pH.
4. Contributions from the UV-absorbing counterions must be minimized. For this reason, mixing of free aromatic bases and acids (instead of salts) to generate a two-component IPD reagent is important. This procedure minimizes the dilution of UV-absorbing components by nonabsorbing extraneous spectator ions. Thus, a pH range of 6–7 appears to be favorable because this range minimizes the contribution of $H^+$ and $OH^-$ ions (generated from the buffer), which in turn improves the detectability.
5. The light-absorbing reagents should not contain spectator ions that need to be detected in the sample. For example, the bromide salt of cationic IPD reagents will exhibit a negative system peak where bromide normally migrates in the electrolyte. This negative peak not only decreases the sensitivity for bromide but may also cause difficulties with integration of analytes migrating closer to bromide.$^{(36)}$
6. The absorbance match of the IPD reagents should be as close as possible (i.e. $\Delta A$ should be minimum) so that neither the cation nor the anion is masking the absorbance of the other ion.
7. The total background absorbance should be additive and be within the linear range of the UV absorbance detector.
Some of the above-mentioned criteria were first evaluated by Shamsi and Danielson. Benzylamine or pyridine bases were mixed with NMS or PTS to generate four different combinations of two-component IPD reagents. For the selection of a suitable wavelength for both IPD reagents (point 4), the background absorbance of 5 mM each of benzylamine, pyridine, PTS, or NMS was measured from the readout of the CE detector by flushing the capillary with light-absorbing solutions.

The cation–anion background absorbance ($\Delta A$) values for two combinations of electrolytes (benzylamine–PTS and benzylamine–NMS) were determined as a function of wavelength in 1–2 nm increments over the range 200–220 nm. The authors found the $\Delta A$ values to be $+3 \text{ mAU}$ and $-61 \text{ mAU}$ using benzylamine–PTS and benzylamine–NMS electrolytes at its minimum interference wavelength of 200 nm. Using this approach the authors compared the electropherogram obtained for the simultaneous separation and IPD of a 15-component mixture of cationic and anionic surfactants. As shown, the benzylamine–NMS electrolyte improved the detection of anionic surfactants because of the negative $\Delta A$ value (Figure 24b), but benzylamine–PTS detected cationic surfactants better, as predicted by the positive $\Delta A$ value (Figure 24a).

### 4.2 Selection of a Suitable pH

As discussed earlier (point 4, section 4.1) simultaneous separation and indirect detection should be optimized by a judicious selection of electrolyte pH. This is because not only the detection sensitivity but also the mobility of cationic and anionic IPD reagents and solute ions, and the magnitude of the electroosmotic flow, are affected by a change in the pH of the IPD solution. Xiang and Li verified experimentally the effect of pH using a seven-component model mixture of inorganic cations and anions. A series of electropherograms obtained using pH values of 4.52, 5.00, 5.42, 6.00, 6.52, 7.04, 7.53, and 8.03 are shown in Figure 25 on the same sensitivity scale. As the pH value is increased, the peak efficiency of anionic solutes is increased. It is apparent that only two out of five anionic solutes could be detected when the pH was less than 6.00 (Figure 25, spectra a–c). On the other hand, resolutions for both cations and anions were not feasible at pH > 7.50 (Figure 25, spectra g and h). Thus, as predicted earlier by Shamsi et al., and verified experimentally by Xiang et al., the use of pH 6–7 (Figure 25, spectra e and f) seems to be the best pH range for the joint separation and IPD of anions and cations.

### 4.3 Effect of Indirect Photometric Detection Binary Electrolyte Concentration

Xiong et al. studied the effect of a two-component IPD electrolyte (imidazole and sulfosalicylic acid) concentration at constant pH on the selectivity of cation and anion separation. They determined that by increasing the total IPD electrolyte concentration, selectivity for the separation of cations and anions (within their individual groups) increased at pH 6.52 and 7.04. However, it was also clear that the enhancement in cation selectivity was not as significant as that for anion separation. Moreover, it was found that when the total IPD electrolyte concentration at constant pH on the selectivity of cation and anion separation.
concentration was greater than 5.0 mM (with imidazole concentration higher than 4 mM) the migration times of more slowly migrating anions (e.g. ClO₃⁻ and ClO₄⁻) increased rapidly. The authors concluded that a higher pH is advantageous for anion separations, but higher total electrolyte is deleterious to the same separations. Xiong et al. further elaborated on this issue by utilizing an imidazole–benzenesulfonic acid system at two different ionic strengths (Figure 26). Although the electroosmotic flow generated under these two conditions was roughly the same, i.e. $79.5 \times 10^{-5}$ and $75.4 \times 10^{-5}$ cm$^2$ V$^{-1}$s$^{-1}$ at pH 6.54 and 7.03, respectively, the migration times for anions were significantly increased at higher total IPD electrolyte concentration. Perhaps the counteracting effect of pH and total IPD electrolyte concentration should be considered when a simultaneous separation is performed.

### 4.4 Simultaneous Separation of 22 Anions and Cations in a Single Run

Using the third approach discussed early in section 4, Kuban and Karlberg reported an impressive simultaneous CZE separation of cations and anions with IPD in less than 5 min (Figure 27). It is noteworthy that this is the highest peak capacity reported so far for the combined separation and IPD of these fast-moving ions. Unfortunately, using the same buffer recipe, transition metals and some alkaline earth metal ions (e.g. Ba$^{2+}$) cannot be analyzed because the cations tend to precipitate as
36 ELECTRONIC ABSORPTION AND LUMINESCENCE

Figure 26 Separation results of the model sample mixture in imidazole–benzenesulfonic acid background electrolyte at different pHs and total electrolyte concentrations: (a) pH 6.54, 4.23 mM total electrolyte concentration (2.77 mM imidazole; 1.46 mM benzenesulfonic acid), 2.0 µA; (b) pH 7.03, 7.65 mM total electrolyte concentration (5.70 mM imidazole; 1.95 mM benzenesulfonic acid). Current $D^+$: 5 µA; voltage $D^+$: 0 kV; ambient temperature; detection at 214 nm; injection for 30 s; capillary $D^+$: 40 cm (32 cm effective length). Peaks (ppm): 1, K$^+$ (5.9); 2, Na$^+$ (16.8); 3, Li$^+$ (4.3); 4, water dip; 5, HPO$_4^{2-}$ (4.4); 6, F$^-$ (3.7); 7, HCOO$^-$ (4.3); 8, ClO$_4^-$ (5.9); 9, ClO$_3^-$ (4.3). (Reproduced from Xiong and Li$^{148}$ by permission of Wiley–VCH.)

Hydroxides or react with the chromate ion. Alternative electrolytes therefore need to be developed for such ionic separations.

4.5 Selected Applications

Simultaneous determination of small cations and anions appears to be an efficient analytical method for “total ion analysis” in a variety of aqueous samples. Electrophoretic analysis of cations and anions in mud and milk samples was described by Kuban and Karlberg.$^{149}$ The dialyzed milk and mud samples were injected into the CE separation system and the total number of ions were analyzed in less than 5 min with RSD < 0.3% for migration times. In addition, good correlation was obtained between IC and capillary ion analysis data for simultaneous analysis of cations (K$^+$, Na$^+$, NH$_4^+$, Ca$^{2+}$, Mg$^{2+}$) and anions (Cl$^-$, SO$_4^{2-}$, NO$_3^-$, HCO$_3^-$) in tapwater and rainwater. Cations and organic acids in soft drinks (apple, orange, and grape juices) have also been determined using 1,2-dimethylimidazole–trimellitic acid with 6 mM 18-crown-6 as binary IPD reagent.$^{147}$ However, the matrix effect strongly influenced the migration of some organic acid (e.g. citrate). The researchers concluded that this is probably due to differences in the viscosity of the injected samples, which influenced the electroosmotic flow.

5 INDIRECT FLUORESCENCE DETECTION IN CAPILLARY ELECTROPHORESIS

Although the discussion thus far has concentrated on CZE/IPD, IFD also offers a means to detect analytes, even when they do not provide a signal at a given detector. In this type of detection, fluorescing ions rather than absorbing ions are used as the CZE electrolyte, and hence a large fluorescence background is always present when the excitation laser interacts with the solution flowing through the detection region. When the analytes appear in the detection region, displacement of the fluorophore ion by an analyte leads to a quantifiable change in the background fluorescence intensity that...
translates to a negative peak. A simple form of fluorescence displacement is based on the displacement of charged analyte ions by fluorescing ions with the same charge on a regular equivalent-per-equivalent basis due to the requirement of electroneutrality. Other alternative displacement processes also exist, but charge interaction appears to be the most efficient. Similarly to indirect absorbance detection, IFD also can be considered as a universal detection scheme for CZE. It is pertinent to comment that the technique of capillary zone electrophoresis/indirect fluorescence detection (CZE/IFD) has been discussed in detail and in depth, in terms of basic principle and instrumentation, in some excellent monographs.\(^{151–154}\)

### 5.1 Factors Influencing Indirect Fluorescence Detection Response

The sensitivity attainable with IFD depends on instrumental considerations. Although lamp-based fluorimeters have been reported for IFD of alkali and alkaline earths ions,\(^{155}\) inorganic anions,\(^{146,156}\) and triorgano tin compounds,\(^{157}\) a more spectacular detection limit is observed when lasers are used as the excitation source.\(^{151–154}\) However, unlike an absorption detector (where the background signal is very stable compared to the measured signal), background fluorescence signals in IFD fluctuate due to the inherent instability of lasers. In addition, fluorophores bleaching upon irradiation with the laser beam is a problem. Despite the high cost and complex operation of the lasers, a \(C_{\text{LOD}}\) that is an order of magnitude better (i.e. \(10^{-7}\) M) than IPD is disappointing.

In addition to the instrumental considerations discussed above, detector response in IFD also depends on some chemical considerations. These include: concentration and type of the fluorescent reagent (also known as the IFD reagent); \(pH\) of the electrophoretic medium; and ionic strength of the buffer. According to Yeung and Kuhr,\(^{151}\) IFD in CZE appeared to be more beneficial than the IPD method at a lower concentration of the visualization reagent. This is because the DR for IPD will decrease with a decrease in the following parameters: chromophore concentration; molar absorptivity; and pathlength (see Equation 1, section 1.3). Although the magnitude of fluorescence intensity also drops with a reduction in the aforementioned parameters, a high value of the DR over a wide range of concentration is still maintained in IFD due to the large signal generated from laser excitation. The observation of Yeung and Kuhr is consistent with recent reports published by a number of workers. For example, Andersson et al.\(^{57}\) found that IFD is more attractive than IPD when the concentration of the fluorophore (e.g. salicylate) is less than 2 mM. Desbène et al.\(^{158}\) also studied the response sensitivity of IFD by varying the concentration of fluorescein over the range \(10^{-4}–10^{-8}\) M. Potassium \(N\)-butylbenzenesulfonate was used as a test sample because its electrophoretic mobility was closer to the mobility of fluorescein. The researchers reported the best compromise concentration for IFD sensitivity to be \(10^{-5}\) M fluorescein sodium salt.

As outlined by Garner and Yeung,\(^{154,159}\) there are five important considerations in the selection of IFD reagents:

1. The fluorophore that should serve as a detection reagent should have a large molar absorptivity for the excitation wavelength available. This is critical if a laser rather than a lamp is used as an excitation source.
2. The quantum efficiency of the fluorophore should be as high as possible.
3. The fluorophore should be soluble and inert in the running CZE solvent system.
4. For the optimum value of \(TR\) (Equation 1, section 1.3) the fluorophore should be fully charged with a preferable charge of unity, and present at as low a concentration as possible.
5. The fluorophore should have minimum adsorption on the walls of the capillary because any adsorbed material will not participate in the charge displacement process.

Based on these considerations, the authors first studied fluorescein as the IFD reagent for the detection of aspartic acid and glutamic acid\(^{161}\) after their separation by CZE. Even without stabilizing the laser source, mass limits of detection (ca. 2 fmol) were reported for the two amino acids.

The sensitivity of IFD is also dependent on the stability of the fluorescence reagent at a given pH; therefore, it is important to select a pH range where the fluorescent intensity of the IFD reagent is constant. Garner et al.\(^{159}\) first studied the effect of \(pH\) on the fluorescence signal of fluorescein. They reported that an increase in \(pH\) from 7 to 9 resulted in a very unstable baseline, presumably due to the interaction of fluorescein with the capillary wall. The researchers then switched to Coumarin 343, a fluorophore with good water solubility, high molar absorptivity (\(2 \times 10^{4}\) at an excitation wavelength of 242 nm) and high quantum yield. Unlike fluorescein, a relatively high \(pH\) stability of this coumarin was found, with some degradation above \(pH\) 11.5. The authors demonstrated excellent mass sensitivity by detecting fructose at the 2 fmol mass level. This was accomplished using 5-\(\mu\)m i.d. capillaries, which is a very difficult task with lamp sources. In the same report, Garner et al.\(^{159}\) described why IPD and IFD analyses of carbohydrates
are limited by Equation (10):

\[
TR = \alpha [\text{sugar}] / [\text{FL}^- + \text{OH}^-]
\]  

(10)

According to Equation (10), at a constant concentration of chromophore or fluorophore \([\text{FL}^-]\) and carbohydrate [sugar], the TR is affected by the values of \(\alpha\) (the fraction of carbohydrate in ionized form) and \([\text{OH}^-]\) (the concentration of hydroxide in solution). Thus, \(\alpha\) in the numerator and \([\text{OH}^-]\) in the denominator are competing functions of pH. Consequently, the total TR (TR\(_{\text{total}}\)) goes through a maximum if it is plotted as a function of pH. The maximum in this plot is the optimal pH for IPD or IFD. However, carbohydrates that have a strong negative charge at lower pH (e.g., phosphorylated and sulfated sugars) are best optimized at lower pH where the effect of hydroxide ion in Equation (10) is minimized. Desbène et al.\(^{158}\) reported that the fluorescence intensity of fluorescein first increases as the pH is raised from 4 to 8, and plateaus only in the highly basic pH range of 8–10. For optimum detection sensitivity the authors recommend a pH of 9.2, where the fluorescence intensity of fluorescein was a maximum and the electroosmotic flow was stabilized. This result obtained by Desbène et al.\(^{158}\) is in disagreement with the earlier report of Garner et al.,\(^{159}\) who found an erratic baseline when

Figure 28 Effect of pH on the separation, sensitivity, and direction of the fluorimetric signal of a mixture of 21 inorganic anions and organic acids. Electrolyte consisted of 20 \(\mu\)M FMN in 100 mM \(\text{H}_3\text{BO}_3\) and 2 mM DETA, adjusted to various pH values with 1 mM NaOH. All anion peak concentrations are 2 mg L\(^{-1}\) for inorganic anions and 5 mg L\(^{-1}\) for organic acids. Peaks: (1) bromide, (2) chloride, (3) nitrite, (4) nitrate, (5) chromate, (6) sulfate, (7) oxalate, (8) molybdate, (9) tungstate, (10) malonate, (11) fluoride, (12) fumarate, (13) formate, (14) succinate, (15) malate, (16) citrate, (17) tartrate, (18) phosphate, (19) hypophosphate, (20) phthalate, (21) carbonate. Pressure injection for 4 s at pH 7.8–8.6 and for 8 s at pH 9.0; voltage of \(-15\) kV applied for separation; current varied from 7.0 to 41 \(\mu\)A. (Reproduced with permission from Shamsi et al.\(^{160}\))
fluorescein was used at pH 9.0. The discrepancy may be due to the fact that a temperature-controlled commercial CE system equipped with a stabilized laser source was employed in the former study. Very recently, Shamsi et al.\textsuperscript{(160)} reported a loss in S/N for inorganic anions using flavin mononucleotide (FMN) fluorophore at pH values greater than 8.0. Because FMN shows a stable response in the pH range of 3.5–8.0,\textsuperscript{(161)} one would expect a reduction in fluorescence response at the weakly alkaline pH values. The situation was a bit more complicated, however, when peak direction was switched, i.e. positive peaks were observed at pH values such as 8.6 or 9.0. Probably the replacement of OH\textsuperscript{-} as well as FMN by the sample anions could cause a temporary localized decrease in pH. At pH 8.6 or 9.0, this may lead to a fluorescence increase, whereas at pH 7.8 or 8.2 the fluorescence remains quite constant. Therefore, positive peaks (decreased fluorescence) of inorganic anions and organic acids were observed at pH 7.8 and 8.2 and the baseline noise was quite low (Figure 28a,b). In contrast, negative peaks (increased fluorescence) were observed at pH values of 8.6 and 9.0 (Figure 28c,d) due to the more important decrease in OH\textsuperscript{-}. The optimum pH for the best S/N for anions was found to be around 8.0 or lower, where preliminary replacement of FMN by the sample anions causes the signal change.

Finally, the ionic strength of the CZE buffer was also shown to play a major role in evaluating the sensitivity of IFD.\textsuperscript{(158)} In fact, buffers of low ionic strength can be very beneficial because the Joule heating induced by the low operating currents is minimized. However, distortion of the analyte zone with buffers of very low ionic strength is possible. Figure 29 illustrates the reduction in S/N of Li\textsuperscript{+} and K\textsuperscript{+} as a function of the ionic strength of borate buffered at pH 9.2. It is clear that IFD sensitivity was a maximum at a sodium borate concentration of 10 mM. A 10-fold improvement in sensitivity of the cations was observed when the sodium borate concentration was further decrease from 10 to 2.5 mM.

5.2 Applications of Indirect Fluorescence Detection for the Analysis of Ionic Compounds

Although a wide variety of UV-absorbing chromophores are now available for both cation and anion analysis by CZE/IPD, little work has been done to characterize IFD electrolytes for CZE of ionic analytes. This is for two major reasons: the number of fluorophores that can serve as a detection reagent is smaller than the number of chromophores, and fluorophores that have strong emission are large organic molecules with low mobility, resulting in poor selectivity for high-mobility inorganic anions.

Figure 29 Evolution of S/N, in the hydrodynamic injection mode, as a function of the ionic strength of the electrolyte in the mobile phase. Operating conditions: fused-silica capillary 57 cm × 75 µm i.d.; applied voltage = 10 kV; temperature = 30°C; sample mixture of LiNO\textsubscript{3} (10\textsuperscript{-4}M) and KNO\textsubscript{3} (10\textsuperscript{-3}M); electrolyte, Na\textsubscript{2}B\textsubscript{4}O\textsubscript{7} (pH 9.2); fluorescein concentration, 10\textsuperscript{-5} M; fluorimetric detection (λ\textsubscript{exc} = 488 nm, λ\textsubscript{det} = 520 nm). (Reproduced with permission from Desbène et al.\textsuperscript{(159)})

5.2.1 Capillary Zone Electrophoresis/Indirect Fluorescence Detection of Anionic Compounds

In 1988, Kuhr et al. in Yeung’s laboratory first introduced IFD for the CZE analysis of underivatized amino acids, proteins, and nucleosides.\textsuperscript{(162,163)} Later, Yeung’s laboratory further evaluated IFD for an extensively large number of analytes. The anionic compounds for which successful CZE/IPD was developed include inorganic anions,\textsuperscript{(164)} nucleotides,\textsuperscript{(165)} sugars,\textsuperscript{(159)} and tryptic digests,\textsuperscript{(165)} lactate and pyruvate,\textsuperscript{(166)} and more recently free cyanide and related compounds.\textsuperscript{(167)}

Salicylate was the IFD reagent reported for determination of seven common inorganic anions in less than 5 min.\textsuperscript{(164)} Using a 0.25 mM equimolar mixture of salicylic acid and sodium salicylate at a pH of 4.0, detection limits in the submicromolar range (1 × 10\textsuperscript{-7} M) were obtained. The authors found that the same IFD reagent is also useful for the separation of 12 nucleotides in ca. 6 min.\textsuperscript{(164)} However, in order to reduce the electroosmotic flow, the salicylate concentration was increased to 1.0 mM and the pH was decreased to 3.5. In a related paper, Garner and Yeung\textsuperscript{(159)} were able to resolve three sugars (glucose, sucrose, fructose) and seven underivatized amino acids (phenylalanine, alanine, leucine, serine, glutamic acid, aspartic acid, proline) using 1 mM coumarin at pH 11.5.
Although the use of lasers for IFD began as early as 1988, substantial interest has developed recently due to the commercial availability of a laser-induced fluorescence detector for CE. Desbène et al. in a series of two papers have advocated the use of fluorescein for this commercial system. In the first paper, the authors analyzed a mixture containing three transition metals (Fe$^{3+}$, Zn$^{2+}$, and Cu$^{2+}$), three alkaline earths (Ba$^{2+}$, Ca$^{2+}$, and Mg$^{2+}$), and two alkali metals (Li$^+$ and K$^+$). Because the use of fluorescein provides maximum sensitivity at basic pH, a complexing agent such as ethylenediaminetetraacetic acid was added to transform transition metal and alkaline earth metal cations into anionic chelates, so that their interaction with the capillary could be minimized at basic pH. As expected, Li$^+$ and K$^+$ eluted before the electroosmotic flow, whereas the six metal chelates eluted after the electroosmotic flow under the optimized conditions of 10 µM fluorescein and pH 7.5. They rationalized the observations based on the treatment developed by Ackerman et al., who have shown that if the absolute mobility of the analyte is smaller than the mobility of the counterion associated with the chromophore or fluorophore, then negative peaks will be observed, and vice versa. Thus, the observed positive peak for K$^+$ and negative peak for Li$^+$ agree with the theory of Ackerman et al. However, it was not very clear as to why the Fe$^{3+}$ chelate provided a negative fluorescent peak whereas Ba$^{2+}$, Ca$^{2+}$, Mg$^{2+}$, Zn$^{2+}$, and Cu$^{2+}$ chelates showed positive peaks.

In a second paper Desbène et al. separated two mixtures – alkanesulfonates ($C_1-C_{10}$ SO$_3^-$) and alkyl carboxylates ($C_1-C_{12}$ COO$^-$) – under aqueous conditions using 10 µM fluorescein and 5 mM Na$_2$B$_4$O$_7$ at pH 9.2 in about 4 and 7 min, respectively. However, the analysis of fatty acids longer than $C_{12}$ required the use of organic solvents (2-propanol, ethanol, or acetonitrile). The authors found no decrease in background fluorescence, irrespective of the solvent used, until the percentage of organic solvent was lower than 40% (v/v). Beyond this limit, baseline fluctuations and noise were increased substantially. They were able to achieve detection limits as low as 700–800 ppb, and the system was used to establish calibration curves and response coefficients for IFD. Several other groups have continued to extend the utility of fluorescein. For instance, Wang et al. evaluated the feasibility of using nonaqueous solvents in CZE with IFD. C$_6$-C$_{24}$ FFAs differing by only one carbon atom were separated and detected in a highly alkaline methanol–acetonitrile system in combination with fluorescein as the IFD reagent. Similarly, Huang et al. used 1.5 mM fluorescein at pH 9.8 for effective separation and detection of five arsenic compounds (arsenite, arsenate, monomethylarsonate, dimethylarsonate, and phenylarsonate) using CZE with IFD in 8 min. Detection limits in the 0.04–0.16 mg mL$^{-1}$ range were.
reported. Unfortunately, the developed method could not be applied for the analysis of arsenic in groundwater, due to matrix effects.

The CZE/IFD method using salicylate reagent was compared to CZE with direct and indirect UV detection for the determination of isoprenyl pyrophosphate. The researchers reported that IFD was the most suitable detection method that provided the lowest LOD (0.5 µM) and highest separation efficiency (600,000) compared to direct or indirect UV detection. However, the LOD was still not low enough to allow analysis of dilute samples of rat liver.

Very recently, the novel IFD reagent FMN, also known as riboflavin-5’-phosphate, was developed in our laboratories for indirect laser-induced fluorescence detection (ILIFD) of a wide spectrum of anionic compounds. Unlike fluorescein, FMN provided strong fluorescence at both acidic and basic pH values. A CZE separation of 21 inorganic and organic anions in about 20 min was possible for the first time with ILIFD. Figure 31 shows the separation of 21 inorganic anions and organic acids at 5 µM and 30 µM FMN. At 100 µM baseline drift was substantial and the S/N decreased (electropherogram not shown). The optimum concentration of FMN was found to be 30 µM because of a better S/N and a reasonable baseline drift. In addition, the use of methanol provided improved resolution and facilitated simultaneous separation and universal IFD of aliphatic and aromatic anionic surfactants. Using pressure injection, the LOD was 20–30 µg L⁻¹ for inorganic anions, 40–50 µg L⁻¹ for organic acids, 250–500 µg L⁻¹ for P₃, and 500–1000 µg L⁻¹ for alkyl sulfates. LOD was optimized further by at least twofold with electrokinetic injection, and the developed CZE/IFD was applied to the simultaneous analysis of ethoxylated lauryl sulfate and lauryl sulfate in a commercial shampoo in less than 10 min.

5.2.2 Capillary Zone Electrophoresis/Indirect Fluorescence Detection of Cationic Compounds

Unlike anionic separations, IFD of cations by CZE is largely unexplored. A literature survey indicated that the cationic compounds for which successful IFD has been reported include only a few organic cations (alkylamines, alkanolamines, tetraalkylammonium, and alkyltins). Quinine sulfate excited with an argon ion laser at 350 nm was the first cationic fluorophore studied for the analysis of some alkali and alkaline earth metal ions and several substituted amines. The optimized system used included 0.38 mM quinine sulfate as IFD reagent and 0.58 mM H₂SO₄ to create a pH of 3.7. Because quinine sulfate is a relatively low-mobility cation, the later-eluting peaks (diethylamine, diethanolamine, tetraethylammonium, and trishydroxymethane) were taller and sharper than those for early-eluting ions (ammonium or dimethylammonium). This pattern of peak profiles in IFD was consistent with the theory developed on peak shapes for CZE/IFD.

In a recent paper, Church et al. have also demonstrated the potential of quinine sulfate in combination with 0-HIBA for the separation and ILIFD of lanthanide ions, including La³⁺, Ce³⁺, Pr³⁺, Nd³⁺, Sm³⁺, and Eu³⁺, in the low-ppb range (6–11 µM). An impressive LOD was possible due to the combination of electrokinetic injection and transient isotachophoresis, which enabled the metal cations to stack into more concentrated zones.

Underivatized amino acids as positively charged ions were investigated using a semiconductor laser with an excitation source of 670 nm. Three potential dyes (methylene blue, rhodamine, and oxazine 750) that can be excited at 670 nm were evaluated as IFD electrolytes. Among the three dyes studied, methylene blue was found to be the most suitable due to its lesser adsorption on the capillary surface. At a high pH value of 11 the adsorption of methylene blue was reduced further, but the fluorescence intensity was substantially decreased at this pH. Therefore, an acidic pH of 3.80 was used to separate and detect the two amino acids (glycine and proline) via CZE/IFD in ca. 15 min.

A small cationic fluorophore, 2-AP, was investigated for ILIFD of sodium and potassium at attomole levels. Li
and Yeung\(^{(174)}\) reported that the difficulty associated with the determination of these inorganic cations at such low levels is due to their contamination in the environment. After detailed studies, it was realized that particulate contamination was the primary source of interference for the cations. This is because one dust particle contains femtomoles of sodium and potassium because as the particle is inadvertently injected false peaks are obtained. After optimizing the procedure for cell samples they reported the mass LOD of potassium and sodium to be 110 and 70 amol respectively.

The first successful use of a lamp-based source for IFD in CZE was accomplished by Bächmann et al.\(^{(155)}\) for the determination of ammonium and alkali and alkaline earth metals by means of an inexpensive fluorescence detector. This accomplishment was carried out using cerium(III) sulfate excited at 251 nm, with emission collected at a 345-nm cut-off filter. The authors found that in cerium(III) sulfate solution the effective positive charge of Ce\(^{3+}\) is smaller than that in solutions of cerium(III) nitrate and chloride. Their observation was in agreement with the lower values of effective mobilities observed for cations separated by CZE using cerium(III) sulfate compared to cerium(III) nitrate. In addition, the authors recommended cerium(III) nitrate and chloride salts as suitable IFD electrolytes for the measurement of fast-moving cations (e.g. Cs\(^{+}\), NH\(_4\)^{+}, K\(^{+}\)), whereas cerium(III) sulfate was suggested as a better electrolyte for slow-moving cations (e.g. Li\(^{+}\)). Some metal cations in the cola beverage were profiled, with \(C_{\text{LOD}}\) reported in the low micromolar range (0.1–0.3 \(\mu\)M).

Finally, Lee and Whang have recently introduced 6-aminoquinoline as the IFD reagent for trialkyltin compounds.\(^{(175)}\) A CZE separation of trimethyl-, triethyl-, tripropyl-, tributyl-, and triphenyltin with IFD using a nonlaser-based fluorometer was achieved in less than 16 min. A \(C_{\text{LOD}}\) in the range 8–18 \(\mu\)M that corresponds to a mass LOD of 80–180 fmol was obtained. The authors pointed out that the lamp-based IFD is simple and cost-effective, with the added advantage of a wide range of wavelengths available for excitation compared to the laser-based IFD.

### 5.3 Applications of Indirect Fluorescence Detection for the Analysis of Neutral Compounds

Although MEKC can be used easily to separate neutral compounds, indirect detection of these compounds is somewhat problematic. This is because the charge displacement cannot be used to displace the absorbing or fluorescent ion from the analyte zone. One of the most elegant solutions to the problem was provided by Amanakawa and Kuhr,\(^{(176)}\) who introduced the use of anionic SDS as complexing agent to the positively charged quinine fluorophore. The authors observed enhanced fluorescence of the quinine ion because of its ion-pairing with the micelle, leading to a large fluorescent background signal. Upon injection, the nonionic analyte enters the micelle and can disturb the micelle–fluorophore complex. Thus, the background fluorescence is decreased, resulting in a negative peak. Despite the enhancement of the background fluorescence intensity of quinine sulfate, no significant shift in the maximum of the quinine emission was observed in the presence of SDS. A pH of 6.80 with 0.50 mM quinine sulfate and 100 mM SDS provided the separation of a mixture of five aliphatic alcohols in less than 8 min (Figure 32). The authors were able to detect phenols with much higher sensitivity (about five times) than aliphatic alcohols, even though the latter group of solutes eluted much earlier than the former. This indicated that the phenolic compounds have a relatively stronger quenching effect and can disturb the micelle–fluorophore complex more efficiently.

Recently, Smith et al.\(^{(177)}\) evaluated three IFD reagents (quinine sulfate, 8-anilinonaphthalene-1-sulfonic acid and N-phenylnaphthylamine (PNA)) in combination with a...
nonionic surfactant (decanoyl-N-methylglucamide) and borate. The authors observed that PNA, the most hydrophobic fluorophore, provided the best sensitivity for IFD. Similarly to the observation of Amankawa et al., the results obtained by Smith et al. also showed an increase in IFD response with an increase in capacity factor of the solute. Figure 33 shows a typical electropherogram of an alkyl phenyl ketone homologous series as evidence for this observation. In addition, Smith et al. demonstrated a linear relationship between peak height and capacity factors, in contrast to a nonlinear behavior found by Amankawa et al.

Kennedy et al. have applied MEKC for the IFD of high explosives. Fluorescein and rhodamine B were evaluated as potential fluorophores. In general, the authors found rhodamine B to be a better IFD reagent than fluorescein because the former resulted in a stable baseline and greater sensitivity. Despite the fact that some explosives could be detected at concentrations as low as \(6 \times 10^{-6}\) M, overall detection sensitivity was poor. The researchers attributed this lack of sensitivity to the laser instability, and suggested the use of a laser power stabilizer as a possible solution to laser noise and baseline drift.

**Figure 33** Electropherogram of alkyl phenyl ketone homologous series. Experimental conditions: running electrolyte, 100 mM borate containing 50 mM decanoyl-N-methylglucamide (MEGA 10) and 0.5 mM PNA, pH 10.0; capillary, 50-cm (detection point) untreated fused-silica, 80 cm (total length) \(\times\) 50 mm i.d.; voltage = 15 kV; excitation wavelength = 365 nm; emission wavelength > 400 nm. Analytes: (1) acetophenone \((n = 0)\), (2) propionophenone \((n = 1)\), (3) butyrophenone \((n = 2)\), (4) valerophenone \((n = 3)\), (5) hexanophenone \((n = 4)\), and (6) heptanophenone \((n = 5)\). Concentration injected: 1 mM of each. (Reproduced with permission from Smith and Rassi.)

Fuchigami and Imasaka accomplished IFD of flavin adenine dinucleotide and deoxyadenosine monophosphate following their MEKC separation. Methylene blue was the IFD reagent and a semiconductor laser emitting at 670 nm was used as the excitation source. This indirect fluorescence detection/micellar electrokinetic chromatography (IFD/MEKC) method also provided lower mass detection limits (fmol), by several orders of magnitude, than those reported for an HPLC-based method using the same semiconductor laser fluorescence detection.

### 6 OTHER INDIRECT DETECTION MODES

#### 6.1 Indirect Chemiluminescence Detection

The general indirect route to chemiluminescence detection is to use a nonchemiluminescence analyte that will interfere or suppress a chemiluminescence reaction. Thus, inverted or negative peaks are observed if the analytes are detected indirectly due to a decrease from a constant chemiluminescence background. Liao et al. were probably the first to demonstrate the successful use of ICLD in CE. It is well known that the chemiluminescence reaction of luminol with hydrogen peroxide is catalyzed by Cu(II), and the chemiluminescence response is proportional to the concentration of free Cu(II). Liao et al. showed that in the absence of analytes a high and constant chemiluminescence background is maintained when Cu(II) is continuously mixed with the luminol and \(H_2O_2\) in the reaction/detection capillary at pH 10.0. After the CE separation, analytes (e.g., amino acids) enter the reaction zone and complex with Cu(II), decreasing the concentration, and catalytic activity of the free Cu(II). As a result of the postcapillary formation of Cu(II)–amino acid complexes, chemiluminescence intensity is decreased, resulting in a negative peak.

In a subsequent paper, the same authors examined a number of parameters of the ICLD system, including buffer concentration, chemiluminescence reagent concentration, catalyst concentration, \(\alpha\)-cyclodextrin concentration and pH. It was found that the luminol chemiluminescence reaction needs an alkaline pH in the range 9–11. A comparison of high-pH buffers (borate, dibasic sodium phosphate, and carbonate) indicated that 15 mM carbonate at pH 10.0 provides the optimum chemiluminescence emission, leading to the best sensitivity for ICLD of amino acids. They suggested that the use of luminol/\(H_2O_2\) should not exceed 5 mM: 25 mM. This is because a higher concentration of luminol decreases the chemiluminescence intensity. On the other hand, an increase in the concentration of \(H_2O_2\) increases the chemiluminescence intensity. However, bubble formation in the buffer reservoir was a problem due to unsteady
electrophoretic current and a substantial increase in baseline noise. They also observed that the maximum S/N for ICLD is ca. 30 µM CuSO₄. Tartaric acid, which prevented the formation of CuCO₃ or CuOH in alkaline pH was added as an auxiliary reagent to Cu(II). The optimization procedure discussed above resulted in CZE separation with ICLD of 10 amino acids (Figure 34). However, a complete baseline separation of 10 amino acids was not successful. Use of 50 mM α-cyclodextrin and 5% methanol led to improved resolution only at the expense of detection sensitivity. One of the major limitations of ICLD is the sigmoidal nature of the calibration curve, which limits the dynamic range to only about two orders of magnitude. Although, the mass LODs of amino acids was in the 100–140 fmol range, it depended mainly on the formation constants of amino acids with Cu(II). Application of the developed ICLD method was demonstrated by analyzing glutamate in a commercial drink.

A similar ICLD method for catecholamines and neurotransmitters has been studied recently by Zhang et al. The authors found that Co(II) is a better catalyst for chemiluminescence reaction compared to Cu(II). The rationale was based on the fact that the Co(II) possesses a shorter half-life (time required to obtain maximum chemiluminescence intensity), with a fast kinetic reaction leading to a stronger chemiluminescence intensity. On the other hand, the use of Cu(II) with a longer half-life may result in weaker chemiluminescence intensity. Zhang et al. were able to resolve and detect four catecholamines (catechol, epinephrine, norepinephrine, and dopamine) by employing 10 mM SDS, 1 mM luminol and 5 mM borate (as separation electrolytes), with 5 mM H₂O₂–5 µM Co(II) as the chemiluminescence reagent. In addition, mass LODs in the range 22–87 fmol for catecholamines and 9–250 fmol for six amino acids were reported. These detection limits were about two or three orders of magnitude lower than those obtained in HPLC with ICLD.

In summary, the use of ICLD in CE can provide femt mole mass detection limits but it suffers from two major shortcomings: the method of ICLD is useful only for a few organic compounds, therefore one area of key importance is the development of appropriate recipes for electrophoresis buffers and chemiluminescence reagents to separate and detect a variety of non-chemiluminescence inorganic and organic species (metal ions, peptides, proteins and cyclic nucleotides); and in the present design of the CE/chemiluminescence interface it takes ca. 7 s for the solution to flow from the tee to the reaction cell. As a result, the chemiluminescence catalyzed by metal ions decays before it can be used to provide a sufficient background chemiluminescence signal for indirect detection. Hence, the design of a new and improved CE/chemiluminescence interface should help to decrease the half-life required for maximum chemiluminescence signals, leading to lower LODs.

6.2 Indirect Electrochemical Detection

Electrochemical principles appropriate for indirect detection in CE include potentiometry, amperometry, and conductivity. In recent years, only the latter two detection methods have been implemented successfully in the indirect mode in CE.

6.2.1 Indirect Amperometric Detection

The general indirect route to amperometric detection is to use an electrophore-competing ion that is itself electroactive, and to monitor the changes in the concentration of this electroactive species as analyte ions are eluted from the capillary. The earliest and perhaps the only example reported so far in the literature is likely to be the work of Olefrowicz and Ewing, who used 3,4-dihydroxybenzylamine (DHBA) as an electrophore
to monitor the emergence of sample ions by registering a decrease in the background current. The authors used 0.1 mM DHBA and a working electrode held at a constant potential of 0.7 V vs. SSCE, taking advantage of the pH-dependent oxidation behavior of DHBA to orthoquinone as shown in Scheme 1:

\[
\begin{align*}
\text{HO} & \quad \text{OH} \\
\text{N} & \quad \text{H}_3\text{O}^+ \\
\text{O} & \quad \text{N}^+ \\
\text{H}_3\text{O}^+ & \quad 2\text{H}^+ + 2\text{e}^- \\
\end{align*}
\]

**Scheme 1**

A high and constant background current was obtained due to continuous oxidation and a steady flow of DHBA. After the analytes were separated by CE and passed through a detector region, a lower level of oxidizable species was observed in the detection zone. The background current thus decreases, resulting in a negative peak. It is noteworthy that the electrophore needs to be present at a very low concentration only, and may therefore be used in conjunction with a buffered system to achieve reproducible migration times. Figure 35 shows the separation of three nonelectroactive cationic amino acids and three nonelectroactive cationic dipeptides using 2-morpholinoethanesulfonic acid buffered at pH 5.65 containing 0.01 mM DHBA, giving a mass LOD as low as 380 amol for the amino acid arginine.

6.2.2 Indirect Conductivity Detection

Although CE with direct conductivity detection in both suppressed\(^{186,187}\) and nonsuppressed\(^{188,189}\) mode is documented, little work has been done with ICD. Similarly to other indirect methods, ICD in CZE is achieved when the carrier electrolyte has a higher level of background conductivity than the analytes. This means that in order to achieve a sensitive signal for ICD, the conductivities of the carrier and electrolyte co-ions have to differ significantly. On the other hand, CZE separation requires that the mobilities of the analyte and carrier ions should be close to avoid excessive peak spreading. These two contradicting requirements can be compensated partly by increasing the ionic strength of the carrier electrolyte.\(^{188}\) In general, for sensitive detection of high-mobility inorganic anions and cations a low-mobility carrier electrolyte with direct conductivity detection is preferred. In contrast, sensitivities of large cations and anions with low electrophoretic mobilities are much better with ICD.

One of the early reports of ICD in CE is by Gallagher and Danielson.\(^{189}\) To detect low-mobility anionic surfactants (\(\text{C}_x\text{C}_y\text{SO}_3^-\)) and cationic surfactants (tetraethyl-, tetrabutyl-, 2-chloroethytrimethyl-, and tetrahexylammonium), a wide range of inorganic cations and anions were evaluated as ICD electrolytes. The authors found that the S/N for anionic surfactants using \(\text{F}^-\) as an ICD electrolyte was about five times larger than those obtained with \(\text{SCN}^-\), \(\text{Br}^-\) or \(\text{Cl}^-\). Moreover, the S/N for cationic surfactants using \(\text{NaCl}\) was higher than when using \(\text{LiCl}\). Hence, \(\text{NaF}\) was found to be the best ICD electrolyte. The simultaneous separation and ICD of both cationic and anionic surfactants using the optimized concentration of 30 mM \(\text{NaF}\) is shown in Figure 36. For three replicate injections, the RSD of the peak height for cationic surfactant ranged from 0.6 to 2.8%, whereas for anionic surfactants it ranged from 0.07 to 1.1%. A typical detection limit attained by this method was ca. 6 mg L\(^{-1}\)
ELECTRONIC ABSORPTION AND LUMINESCECE

(31.9 µM for C₆ SO₃⁻), which was not as low as that reported for IPD.

Lucy and Wu119) recently confirmed that ICD is most sensitive for low to medium-mobility analytes. For example, using bromide, acetate, and formate counterions, ICD after CZE separation of C₆—C₁₂ SO₃⁻ was possible. Lucy and Wu also showed that the response of conductivity detection is linear for more than two orders of magnitude (5 × 10⁻⁶–5 × 10⁻⁴), with C_LOD as low as 1 µM for C₆ SO₃⁻. Owing to similarities in conductivity and electrophoretic mobility, a response equation was developed and applied to show that the possibility exists for a universal calibration in conductivity detection.

Very recently, Fracassi da Silva and do Lago designed an oscillometric conductivity detector for CE.120) Using this detector, ICD of quaternary ammonium salts was accomplished with potassium acetate as the CZE buffer. The peak sensitivity was found to be proportional to the migration time, e.g. tetramethylammonium ion eluted first and tetrabutylammonium ion eluted last, providing C_LOD values of 10.4 and 4.2 µM, respectively.

## 1 Introduction

The current interest in development of new techniques for analysis is largely attributed to limitations of the more conventional instrumental methods. Classical biomolecule identification usually involves separation of a complex mixture of biological molecules followed by tests for identification of the separated fractions. No single test provides definitive identification of an unknown biomolecule, hence a complex series of tests are required. Such processes are time-consuming and cannot be carried on a reasonable timescale needed in clinical laboratories. These obstacles and the desire to attain adaptability to primitive field test conditions have prompted many researchers to explore modern alternatives to classical instrumental procedures. Most of these modern analytical tools are characterized by rapid data acquisition and data reproducibility which is due to coupling with computer-aided instrument control, data recording and interpretation. A number of modern instrumental techniques have been applied to the identification of biomolecules. These well-established methods include high-performance liquid chromatography (HPLC), capillary electrophoresis (CE), circular dichroism (CD), gas chromatography (GC), and mass spectrometry (MS). Many of these techniques have also been adapted for field applications. Most of these techniques conventionally have been applied in the UV/VIS region. However, the NIR region offers several advantages over the conventional UV/VIS region.

Sir William Herschel, the English astronomer, discovered the NIR region (600–1100 nm) at the beginning of the 19th century\(^1\) by using a prism and a thermometer; however, this region of the electromagnetic spectrum did not receive much attention until the advent and recent availability of inexpensive light sources, such as diode lasers and detectors such as photodiode and avalanche photodiode (APD) detectors. The 600–1100-nm region corresponds to an energy range of 48–26 kcal mol\(^{-1}\). Atomic and molecular transitions in this long-wavelength region are processes that require relatively low-energy photons, because the ground- and excited-state species are close in energy. As a result, several classes of molecules, such as polymethine and phthalocyanine (Pc) dyes, and certain elements, such as ruthenium and osmium, require a moderately low energy input to produce spectroscopically measurable electronic transitions.

Owing to its sensitivity and selectivity, fluorescence is used as a major analytical tool in the identification of target molecules of interest. Typically, this involves using fluorophores as reporter molecules or labels. Background fluorescence from components other than the

Fluorescence is more sensitive and selective than absorbance as a spectroscopic tool, not only because it is measured against a zero background but also because the magnitude of fluorescence signal, $F$, at low dye concentrations is expressed by Equation (1):

$$F = 2.303\theta I_0 e b C$$

where $I_0$ is the excitation power, $\varepsilon$ is the molar absorptivity at the excitation wavelength, $\theta$ is the quantum yield, $b$ is pathlength, and $C$ is the dye concentration. It can be seen that the limits of detection can be improved by a stronger excitation source. Laser-induced fluorescence (LIF) provides a superior approach to improve the sensitivity of fluorescence techniques. However, one must keep in mind that the limit of detection increases only as the inverse square root of excitation power and a strong excitation source can cause photo bleaching of the fluorophore. The limitations of conventional lasers as excitation sources include their high price, size, maintenance costs, and their limited wavelength selection. LIF in the NIR region (600–1100 nm) offers several advantages, and the recent advances in semiconductor laser technology have made the use of lasers more practical. In addition, the extensive use of NIR-emitting laser diodes in the telecommunications industry has made them more readily available. These types of lasers are inexpensive (typically <$150), small (~1 cm), and have a long operating lifetime (~100 000 h). A comparison of selected visible and NIR laser excitation sources is provided in Table 1. The gallium–aluminum–arsenide (GaAlAs) laser diode has drawn much interest because its emission wavelength of 785 nm is compatible with several classes of polymethine cyanine and naphthalocyanine (NPc) dyes that exhibit NIR fluorescence.

In addition to the availability of diode lasers used for excitation, fluorescence detection in the NIR region has advantages since noise resulting from scatter is related to wavelength of detection by the factor of $1/\lambda^4$. Detection at 820 versus 500 nm results in more than a sixfold reduction in scatter noise. The low background interference in the NIR spectral region allows NIR fluorophores to be used as ideal probes in both biological and environmental applications. The advantages offered by the NIR region are summarized in Table 2. Detection in the NIR allows the commonly used photomultiplier tube (PMT) to be replaced with the more efficient photodiode and APD type. The APDs have excellent quantum efficiency in the NIR region. Table 3 illustrates the advantages offered by APDs in comparison with PMTs. These benefits include their low cost, compact structure, and their durability. In addition, they have low internal noise and very low power consumption. All these features allow NIR fluorescence
instrumentation to be highly versatile and amenable to miniaturization. These features aid in the development of a portable compact and rugged instrument for field applications.

The recent progress in solid-state diode laser technology, the availability of commercial NIR absorbing dyes, and the development of diverse synthetic routes to functionalized NIR absorbing dyes have allowed NIR spectroscopy to be used in many diverse applications. These specific uses rely on the response of the chromophore after its excitation by NIR radiation. A simple absorber can be used in spectrophotometric analysis, as molecular probes in immunoassays (IAs), or in applications of security printing, such as laser-readable bar codes. The absorber can re-emit the input energy via fluorescence or phosphorescence. Also, the NIR-absorbing chromophore can convert the excited-state energy into other forms that can be utilized for specific applications. After absorption of laser energy, the chromophore can produce a local heating effect in the medium in which it resides. This technique is used in the optical data recording technologies, such as WORM (write once read many) and DRAW (direct read after writing), full color laser imaging, and in medicinal uses such as tissue welding. Conversion of the NIR radiation into electrical energy by the chromophore is the fundamental basis for photovoltaic cells and electrophotography, including laser printing. Furthermore, transfer of the chromophore’s excited-state energy to endogenous ground-state molecular oxygen is the foundation for the selective destruction of neoplastic tissues in photodynamic therapies. In particular, the NIR region provides a convenient spectral range for photodynamic therapies and in vivo imaging owing to the multiscalar penetration of biological tissues. Taken together, these benefits make NIR analysis an operator-safe, nondestructive, sensitive, and versatile technique that is taking the place of conventional methods, such as radiolabeling. Moreover, dilute samples can be analyzed safely and relatively fast compared with other techniques. Several applications have been developed in the past decade utilizing the various advantages offered by this novel methodology ranging from DNA sequencing, pH and hydrophobicity determination, metal ion detection, antibody (Ab) labeling, HPLC, and high-performance CE.

2 NEAR-INFRARED CHROMOPHORES AND LIGHT ABSORPTION PROPERTIES

To take full advantage of the high-technology NIR instruments, new NIR chromophores with specific properties are required. The comprehension of the color–structure relationship of near-infrared dyes (NIRDs) can provide useful information for their development since the light-absorption property of an organic molecule is correlated with its structural features. A highly conjugated system in either a linear or a cyclic arrangement in the molecule is responsible for the absorption maxima in the NIR region.

In principle, the absorption property of a chromophore is the characteristic of the energy that is absorbed to cause the electronic transition. NIR-absorbing chromophores require relatively low energy for the transition, and this corresponds to the longer wavelength of the electromagnetic spectrum in comparison with UV/VIS absorption. Since the transition energy is the energy required for a single electron to be excited from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO), the closeness between the HOMO and LUMO orbital is primarily responsible for the amount of energy required to induce this electronic transition. Therefore, the shift of the absorption maxima (λ_max) into the NIR region can be induced if the gap between the HOMO and the LUMO orbitals is brought close enough to give the transition energy in the range 48–26 kcal mol⁻¹. In practice, effective structural modification of the chromophore can cause the desired bathochromic shift. Griffiths summarized in detail the general strategies to develop new NIR-absorbing dyes using this approach. These strategies include (i) extending the conjugation of a chromophore, (ii) increasing the interaction between electron donor and acceptor groups within a chromophore, (iii) altering the electronegativity of atoms within a chromophore, (iv) introducing specific branching or bridging within a chromophore, (v) metal complexation with a chromophore, (vi) intermolecular charge-transfer complex formation, and (vii) formation of a free radical that is part of the chromophore.

The Pariser–Parr–Pople molecular orbital (PPPMO) method and XNDO/S method are useful in the estimation of the absorption position of the chromophore that needs to be constructed. The perturbational molecular orbital (PMO) theory in the form of Dewar’s rule
can also aid in the prediction of the light-absorption properties of chromophores with structural changes.\(^8\) This rule is particularly useful in the development of new NIRDs since one can correlate the spectroscopic effects with a structural change at a specific position. In the basic analysis of an odd-alternate system of the conjugated chromophore, each alternate atom starting from a terminal donor is starred, as exemplified in (1). Dewar’s rule implies that an increase in the electronegativity at a starred carbon results in a hypsochromic shift. On the other hand, a bathochromic shift will be induced if the electronegativity of an atom at an unstarred position is increased. In particular, a bathochromic shift of a cyanine chromophore is induced if the electron donor groups at starred positions or electron-withdrawing groups at unstarred positions are introduced.\(^6\) This is further illustrated by the studies of substituted trimethine cyanines (1) on the basis of the PPPMO theory by Yasui et al., which showed the decrease in the electron densities at the starred positions and increase at the unstarred positions of the polymethine chain accompanying the first excitation of (1).\(^9\) An additional example of the application of Dewar’s rule is given in (2) for three heptamethine cyanine dyes of a general structure (2). As can be seen, the electron-withdrawing substituent (CN) at the central unstarred position of the chromophore causes a bathochromic shift and a hypsochromic shift is observed for the electron-donating group (OMe) relative to absorption of the parent unsubstituted dye R = H.\(^10\)

### 3 CHEMISTRY OF NEAR-INFRARED DYES

So far, the theoretical correlation between structure and absorption properties has been discussed. These general rules can also be applied in the practical synthetic design of NIR-absorbing dyes. However, it should be noted that not only the light absorption properties of NIR chromophores but also other characteristics for different analytical applications are desired in the design of these systems. NIR chromophores with proper functional groups, organic and/or water solubility, high molar absorptivity or fluorescence maximum in the NIR region are required for most applications, including medical and optical purposes, dye lasers, and photographic sensitizers. These characteristics can be generally introduced in two ways, namely (i) by the structural modification of commercially available dyes and (ii) by direct synthesis utilizing appropriate precursors. Several examples of direct synthetic routes to NIRDs with specific applications are discussed below.

#### 3.1 Indocarbocyanine Dyes

Functionalized NIR absorbing chromophores are widely used for labeling purposes. However, the commercial availability of such systems is somewhat limited. The first NIR-absorbing dyes containing −N=C=S and −C(O)CH₂I functionalities for selective coupling with amino and thiol groups, respectively, of biomolecules were synthesized by Waggoner’s group\(^11\). These dyes, synthesized by using classical chemistry, contained the reactive group at one of the terminal heterocyclic units, and were extremely difficult to purify. Subsequently, Strekowski et al.\(^12,13\) discovered a facile functionalization of indolium heptamethine cyanine dyes at the central meso position of the chromophore, and the synthesis of (8a–c) is given in Scheme 1 as an example. These dyes are substituted with an isothiocyanato or N-succinimidyl ester function for selective labeling at the amino group of proteins or bioconjugates such as amino-functionalized nucleotides.\(^13,14\) The structural design of (8) includes the presence of sulfonic acid groups for excellent solubility in water and the overall symmetry of the molecule to contribute to the facile purification of the dye by simple crystallization. The symmetry is responsible for a high molar absorptivity of the chromophore. An important structural feature is the rigid trimethylene bridge in the center of the molecule that enhances the fluorescence quantum yield by decreasing conformational freedom of the NIR fluorophore in comparison with that of the fluorophore without the bridge.

The key synthetic step to (8) is a facile nucleophilic displacement of the chloro substituent in the intermediate product (7) which, apparently, involves an SN₁ pathway.\(^12\) In the preparation of (7) the starting material (6) is derived from dialdehyde (11) (for structure, see Scheme 2) by the reaction with aniline. The second component (5) is prepared efficiently by the reaction of (3) and (4), as shown in Scheme 1.

This approach, as discussed above, was utilized by Flanagan et al.\(^15\) in DNA sequencing involving capillary
Scheme 1 Synthetic route to heptamethine dyes. (i) Reflux in 1,2-dichlorobenzene. (ii) Reflux in EtOH in the presence of sodium acetate. (iii) Substituted sodium phenolates or thiophenol in DMF, 23°C. [Strekowski et al. approach.]

**Scheme 2** Synthetic route to heptamethine dyes. (i) Reflux in 1,2-dichlorobenzene. (ii) Reflux in EtOH in the presence of sodium acetate. (iii) Substituted sodium phenolates or thiophenol in DMF, 23°C. [Strekowski et al. approach.]

**Table:**

| a | X = S, R = NCS |
| b | X = O, R = NCS |
| c | X = O, R = CH$_2$CH$_2$CO-N$^-$ |

Their dyes (9a–g) contain different atoms incorporated in the periphery of the chromophore, and have been prepared by substitution of the meso-chlorine atom in the intermediate dye with 2,5-disubstituted phenolates. The introduction of fluorine or heavy atoms such as iodine, bromine, and chlorine into the molecular framework has been found to affect the fluorescence lifetime without affecting the spectral properties of the chromophore. It was reasoned that introduction of heavy atoms induces spin–orbit coupling. As a result, the intersystem crossing (ISC) rates are enhanced producing a reduction in the excited-state lifetimes associated with the singlet state.

Recently, several commercial NIR-absorbing cyanine dyes have also been made available with amine-reactive groups for covalent coupling with synthetically altered nucleotides or oligonucleotides. The dyes are available under the Cy$^{TM}$ and IRD$^{TM}$ trade names, and have been synthesized by Mujumdar et al.$^{[16]}$ and LI-COR, Inc.$^{[17]}$ respectively. The LI-COR IRD$^{TM}$ dyes, such as the nonsymmetric heptamethine dye IRD800$^{TM}$ phosphoramidite [(18), Scheme 2], can be prepared by using the methodology described by Narayanan et al.$^{[18]}$. The synthetic route involves heating the bisaldehyde (11) and the hydroxy-functionalized quaternary indolium salt (10) with azeotropic removal of water (Scheme 2) to give the intermediate ‘half’ cyanine carboxaldehyde (12). This intermediate generated in situ is further allowed to react with indolium alkyl sulfonate (5), which furnishes the cyanine dye (13). The absorption maximum of the NIR chromophore in (13) can then be fine tuned by addition of an electron-donating or electron-withdrawing group at the meso-position, as already discussed. Thus, the reaction of (13) with sodium phenolate (14) furnishes a phenoxy derivative (15). Further treatment of the meso-substituted cyanine dye (15) with 1H-tetrazole (16) and 2-cyanoethyl tetraisopropylphosphorodiamidite
Scheme 2 Synthetic route to IRD800™ phosphoramidite. (i) Reflux in a mixture of benzene and n-butanol with azeotropic removal of water. (ii) Stirring in DMF at 23 °C.

(17) produces the final dye (18) (IRD800™) that contains a reactive phosphoramidite functionality for automated DNA synthesis applications. The spectral properties of IRD800™ are retained after coupling with the oligonucleotide. The unlabeled chromophore (18) exhibits an absorption maximum at 787 nm in methanol with a 25-nm Stokes shift in fluorescence and a 15.0% quantum yield, while the oligonucleotide-labeled chromophore (18) has an absorption maximum at 796 nm in water with a 23-nm Stokes shift and a 14.7% fluorescence quantum yield.

Using similar synthetic strategies, nonsymmetric pentamethine cyanine dyes have been developed by Mujumdar et al. The dyes, such as Cy5-dUTP™ (19), can be covalently linked to biomolecules including nucleotides and the conjugates used in enzymatic polymerization.
processes. The dye-labeled dUTP analogs can be incorporated into DNA probes by nick translation, random priming, and polymerase chain reaction (PCR).

3.2 Squarylium Dyes

In addition to the indocarbocyanine dyes, synthetic routes to indolenine–squaraine dyes, such as the N-succinimidyl ester derivative (23) (Scheme 3) for conjugation to proteins, are being developed. The squarylium dyes exhibit high photostability and quite long fluorescent lifetimes (nanosecond range) in aqueous solutions. Further benefits of using NIR-absorbing squaraine dyes for biological applications include the fact that their spectral properties (absorbance, emission, and lifetime) are independent of pH under physiological conditions (pH 6–9). As shown in Scheme 3, Terpetschnig et al. synthesized a water-soluble NIR-absorbing dye containing an activated ester moiety. The reaction of (20) and (21) produced carboxy-substituted dye (22). Following purification by preparative thin-layer chromatography (TLC), the nonsymmetric squaraine (22) was coupled to N-hydroxysuccinimide to produce the active ester (23).

3.3 Phthalocyanines and Naphthalocyanines

The NIR-absorbing dyes such as Pc and Npc type are used as industrial colorants and in special applications of electronics and optics. They efficiently complex various metal ions, and approximately 70 central metal ion species of PCs are known. The cation is held in the planar 18-electron cavity and the metal cation can strongly influence the physical and spectral properties of the dye, including absorbance, emission, and fluorescence lifetime. These NIRDs are sensitive to environmental changes such as pH and metal concentration. Classical synthetic routes to metal ion-containing Pc dyes [metal ion phthalocyanine (MPc) dyes] are illustrated in Scheme 4 where the metal ion acts as a central template for cyclotetramerization. As can be seen, MPc (28) is obtained directly from diiminoisoindolenine (24), phthalic anhydride (25), phthalonitrile (26), or phthalimide (27) in the presence of a metal salt. These dyes, though highly insoluble, are extremely stable and can be obtained by precipitation and further purified by sublimation. Metal ion-containing
One approach to overcome the insolubility is to incorporate sulfonate groups into the periphery of the existing PCs or NPCs (Scheme 5). Patonay et al. at Georgia State University have synthesized a tetrasulfonylated aluminum NPC (31) that can be incorporated into an optical probe for NIR metal determinations. Once incorporated into the fiber, the four sulfonate groups at the periphery of the NIR fluorophore interact with metal ions, such as K+, to produce spectral changes in their absorption maximum (λ<sub>max</sub>) and/or fluorescence intensity. The NIR probe studied by Patonay et al. provides metal detection over the range 1 × 10<sup>−8</sup>−0.5 × 10<sup>−1</sup> M.

### 4 ANALYTICAL APPLICATIONS OF NEAR-INFRARED FLUORESCENCE

LIF offers tremendous advantages over conventional analytical methods. The NIR region which has no background interference when coupled with LIF can attain sensitivities obtained by radiolabeling. This method also provides a step towards the maximum achievable sensitivity, that is, single-molecule detection. Many reviews of NIR fluorescence that describe dyes, instrumentation, and applications are available. An authoritative review, though dated, is provided by Warner et al. A recent book summarizing the results of a North Atlantic Treaty Organization (NATO) Advanced Research Workshop covers the synthesis, optical properties and applications of selected NIRDs in high-technology fields. In the next section, representative examples are reviewed to emphasize and acknowledge further the advantages and usefulness of NIR fluorescence techniques.
4.1 Applications of Non-covalent Labeling with Near-infrared Dyes

The NIRDs used as reporter molecules can be attached to the biomolecule of interest by two methods, via (i) covalent bond and (ii) noncovalent hydrophobic and/or ionic interactions. Theoretically, the hydrophobic backbone of many NIRDs allows for noncovalent labeling of large biomolecules. However, only a limited number of practical applications have been tested.

\]

One of the earliest applications studied was the binding of indocyanine green (ICG) (32) to serum albumins by Kamisaka et al. in 1974.\(^\text{25}\) Similar studies by Sauda et al.\(^\text{26}\) using semiconductor laser fluorimetry illustrated that human serum albumin labeled with ICG provided picomolar detection limits. A comparison of noncovalent [\((33)\) and \((34)\)] and covalent dyes [\((35)\)] labeling used in HPLC determination was investigated by Williams et al.\(^\text{27}\) in terms of stability and specificity. Their results indicated that noncovalent labeling occurs rapidly at a physiological pH range. However, this interaction was found to be nonspecific and less stable than covalent binding.

4.2 Bioanalytical Applications of Covalent Labeling with Near-infrared Dyes

Many bioanalytical applications which rely on covalent labeling have been developed. Techniques that utilize this methodology include IAs, CE, DNA sequencing, and the development of gene probes.\(^\text{28}\) This section details some of these applications with their associated merits and disadvantages.

4.2.1 Application of Near-infrared Fluorescence in Capillary Electrophoresis

Analytical separations of intact proteins using HPLC and CE have been shown to have excellent resolving power.\(^\text{29}\) CE is particularly advantageous for protein analysis because of its higher chromatographic efficiency, faster separations time, and ability to use small amounts of material. The low molecular diffusion rates of proteins help achieve theoretical plate numbers as high as \(10^6\).

Many excellent reference books on CE have appeared in recent years,\(^\text{30–32}\) and the reader is encouraged to refer to them for additional information not covered below. The *Handbook of CE*\(^\text{31}\) is very thorough, while the CE primer series offered by Beckman Instruments\(^\text{30}\) provides a brief overview of the principles of different separation techniques for a variety of applications.

Five main modes of electrophoresis have been developed over the years. These include capillary zone electrophoresis (CZE), isoelectric focusing (IEF), CGE, isotachophoresis (ITP), and micellar electrokinetic chromatography (MEKC). These different modes account for the wide applicability of CE to different analytes. However, one of the challenges in CE applications is the detection of analytes at low concentrations. This is a result of the physical dimensions of the capillary used for separation. Typical injection volumes in the nanoliter range combined with small detector windows of approximately 100–200 mm require highly sensitive detection systems.

UV/VIS absorbance is the most commonly used detection method for CE. The advantage is simplicity, low cost, and ease of use. Detection limits are in the range of \(10^{-13} – 10^{-15} \text{ mol}\) for direct absorption (a factor of 10 less for indirect methods). Other methods employed include MS, electrochemical, refractive index and radiometric detection.\(^\text{28}\) Fluorescence detection can greatly enhance the sensitivity of CE methods. For example, direct fluorescence provides detection limits in the range of
10^{-15} \text{ to } 10^{-17} \text{ mol} (a factor of 10 less for indirect methods). However, the number of compounds that fluoresce naturally is limited and derivatization of analytes with a fluorescent tag is frequently required. Fluorescence emission is measured against a zero background signal, resulting in improved detection limits in comparison with absorption methods. Furthermore, LIF coupled to CE provides a sensitivity of approximately $10^{-18} \text{ to } 10^{-22} \text{ mol}$. This improved sensitivity of fluorescence detection is attributed to concentrating high power monochromatic light into a very small area, which provides an ideal excitation source for CE fluorescence detection.

LIF is one of the most sensitive methods of detection available for use with CE. Although the number of publications on the subject has been rising steadily each year, the practical use of LIF with CE has been limited owing to scatter from incident light reflected by the capillary walls with on-column LIF detection. Scatter can be greatly reduced by using postcolumn detection using a sheath-flow arrangement, first described by Chen and Dovichi. However, this set-up adds a significant amount of complexity to the method, requires additional equipment such as a low-flow HPLC pump, and is not commercially available. Another deterrent is the high cost associated with visible lasers which are suitable for excitation of the more popular fluorescent labels including fluorescein isothiocyanate (FITC) and 3-(4-carboxybenzoyl)-2-quinolinecarboxaldehyde (CBQCA).

Several authors have reported on the advantages of using semiconductor lasers with CE. Most investigations to date have involved the use of far-red fluorescent dyes. Williams et al. described a diode laser-based indirect absorbance detector for the analysis of a series of tetraalkylammonium ions. In this study, rhodamine 700 ($\lambda_{\text{abs}} = 642 \text{ nm}, \lambda_{\text{em}} = 668 \text{ nm}$) was used as a background absorber, and detection limits were found to be of the order of 20 mM. Another study utilizing a time-resolved photon counting fluorimetry CE method was described by Song et al. Four fluorescent dyes were evaluated using an LIF detector with a 74-ps pulsed semiconductor laser emitting at 655 nm. The dyes investigated included methylene blue ($\lambda_{\text{abs}} = 665 \text{ nm}, \lambda_{\text{em}} = 685 \text{ nm}$), oxazine 725 ($\lambda_{\text{abs}} = 655 \text{ nm}, \lambda_{\text{em}} = 679 \text{ nm}$), 1,1',3,3',3'-hexamethyl dicyanovarins (HIDC) iodide ($\lambda_{\text{abs}} = 636 \text{ nm}, \lambda_{\text{em}} = 667 \text{ nm}$), and rhodamine 700. The lowest limit of detection was reported to be 2 fmol, which was obtained for oxazine 725 at a concentration of $0.2 \times 10^{-5} \text{ M}$. Fuchagami et al. synthesized a novel far-red fluorescent labeling dye for use with a semiconductor LIF detector. Several amino acids were derivatized with 9-cyano-N,N,N',N'-triethyl-N\text{'}-S\text{'}-succinimidolysisocarbonylpentyl)pyronine chloride ($\lambda_{\text{abs}} = 663 \text{ nm}, \lambda_{\text{em}} = 685 \text{ nm}$) and were separated and detected by CE. The experimental system used a 2-mW semiconductor laser emitting at 660 nm and a PMT detector. Detection was performed off-column using a sheath flow cell to reduce Rayleigh scatter, achieving a limit of detection [signal-to-noise ratio (SNR) = 2] of 800zmol.

The advantages of using APD CE detectors at wavelengths above 650 nm have been reported. Kawazumi et al. compared PMT and APD detection using oxazine 725 excited by a 29-mW semiconductor laser emitting at 655 nm. The APD was operated in a near-Geiger mode with time-gated detection, resulting in a 47-atom limit of detection. The APD limit of detection was 98 times greater than that with a PMT. As already mentioned, detection in the NIR region offers considerable advantages over working in the conventional UV/VIS region.

A significant amount of work with NIR fluorescent dyes including their applications to CE has been conducted at Louisiana State University by Soper et al. They observed bursts of photons from single NIR fluorescent molecules in a flowing stream using a Ti: sapphire laser (12 mW) and an APD detector. The dye infrared (IR)-132 ($\lambda_{\text{abs}} = 805 \text{ nm}, \lambda_{\text{em}} = 847 \text{ nm}$) at a concentration of 25 fM in methanol was used in these experiments with time-gated off-column detection. A comparison of a single-molecule detection of visible (R6G) dye and the NIRD IR-132 (Table 4) shows a significant reduction in background fluorescence, resulting in a lower discriminator threshold and error probability, and thereby provided a higher single-molecule detection efficiency in the latter case. A set-up similar to the photon burst experiment, using continuous excitation and CE with on-column detection, was utilized for an investigation of binary solvent effects in CZE with several NIRDs and dye-labeled amino acids. One of the dyes substituted with an isothiocyanate group (37), was synthesized from dye (36) by Soper et al. and covalently bound to amino acids. The results showed that the detectability, efficiency, and resolution of the

amino acid was 21 zmol, using a 1:9 methanol, and the limit of detection of a dye-labeled fluorescein primer (NIRD-labeled CGE) and DNA sequencing applications. A comparison was used to evaluate NIR fluorescence detection for use with a 10-mW Ti:sapphire laser emitting at 795 nm in a 9:1 methanol–water buffer. A comparable CE system to be 0.4 zmol using the dye HDITCP (Table 5). However, cationic NIRDs were found to be problematic at low concentrations owing to capillary wall adsorption. The on-column limit of detection was found to be 0.4 zmol using the dye HDITCP ($\lambda_{abs} = 780$ nm, $\lambda_{em} = 825$ nm) at a concentration of $2 \times 10^{-10}$ M in 95% methanol, and the limit of detection of a dye-labeled amino acid was 21 zmol, using a $1 \times 10^{-9}$ M solution in a 9:1 methanol–water buffer. A comparable CE system with a 10-mW Ti:sapphire laser emitting at 795 nm was used to evaluate NIR fluorescence detection for CE and DNA sequencing applications. A comparison between detection for NIRD-labeled primer (38) and fluorescein labeled primer (39) is shown in Table 6. Under similar conditions, the significantly lower Raman contributions and background fluorescence resulted in a background of 10,000 counts for NIRD compared with 200,000 counts for visible excitation in contrast to the larger detection efficiency at 800 nm in comparison with 550 nm. Although the NIRD exhibits a lower quantum efficiency, a much lower limit of detection of 34 zmol was achieved for an IRD41 labeled M13 primer ($\lambda_{abs} = 786$ nm, $\lambda_{em} = 812$ nm) in comparison with 1.5 amol for the visible primer primarily owing to the significantly smaller background in the NIR region.

Until recently, all near-infrared laser-induced fluorescence (NIRLIF) work completed to date involved the use of laboratory-made CE systems and detectors. However, two commercial LIF detectors are currently available for use with CE, manufactured by Beckman and Zeta Technology. The Beckman LIF detector is specifically designed for use with their P/ACE CE instrument, while the Zeta LIF detector is a general-purpose detector also applicable to HPLC use. Both detectors are optimized for use in the visible region and utilize PMT detectors, with laser excitation via a fiber-optic cable. Recently, Patonay et al. at Georgia State University, actively involved in research in other areas of NIR fluorescence, developed a simple interface between a commercial APD-based NIR-LIF detector and a CE instrument. The system retained the fully automated injection, separation, and data collection capabilities of the commercial CE instrument and was optimized for detection around 820 nm with laser excitation at 787 nm, where the detector sensitivity was improved about 400-fold in comparison with the conventional PMT-based LIF detector.

To illustrate the challenges in design of developing a NIR fluorescence detector interface to exploit fully the advantages offered by this region, a more detailed description of the work done by Baars et al. (28) is presented in the following section. A Beckman LIF detector with the P/ACE 5000 CE instrument was modified to accommodate the diode laser excitation and NIR fluorescence detector. The back mounting plate and a portion of the self-aligning beam probe assembly of the Beckman LIF detector was used in the interface. The flat mirror, filter holder, PMT and detector electronics were removed resulting in a collimated fluorescence output from the LIF cartridge, passing through the beam block and beam probe, to allow interfacing with the NIR detector. A proprietary microscope and laser assembly manufactured by LI-COR, Inc. (Lincoln, NE, USA) was used as the NIRLIF detector. This detector system is comparable to components used in the commercially available automated DNA sequencing instrument (41) (LI-COR Model 4000), with the exception of modified focal length optics and an extra band-pass filter. The laser assembly for excitation contained a GaAlAs laser diode emitting around 787 nm (20 mW peak power, modulated with a 50% duty cycle) and a focusing lens (focal length $f = 46$ mm). The detector consisted of a three-stage Peltier-cooled APD. The detector assembly contained a plano-convex lens ($f = 31$ mm) to collect the fluorescence image, three identical band-pass filters (825 ± 15 nm)
to reduce background noise from laser scattered light (Rayleigh), and a second plano-convex lens \( (f = 31 \text{ mm}) \) to refocus the signal on to the APD photoactive area (0.5 mm diameter). The interface between the LIF cartridge and the NIR fluorescence detector comprised an aspheric condenser lens mounted immediately past the beam probe assembly. An 800-µm circular aperture was installed at the focal point of the condenser lens to reduce stray light. The NIR detector was fixed to an \( x-y-z \) micrometer stage installed on the mounting plate and focused on the image produced by the interface lens. The diode laser was disconnected from the LI-COR microscope assembly and was mounted on another \( x-y-z \) micrometer stage mounted on the side of the CE base. The laser signal was focused directly on the excitation fiber, resulting in a 4 mW average excitation power at the capillary interface. The optical path of the complete system is shown in Figure 2.

Fluorescence emission was collected by the mirror and reflected as a collimated beam at 180° from the angle of excitation and the collimated beam was then focused by the aspheric condenser lens to the appropriate image size, at the focal length of the detector. The detector optics filter the fluorescence signal through three band-pass filters prior to focusing the signal on the window of the APD detector. Instrument control and data collection of the P/ACE™ 5000 CE system were fully automated through the Beckman System Gold chromatographic software (version 8.01), run on a 486-33 personal computer. The detector signal was interfaced with the chromatographic software. This was accomplished by connecting the analog detector output to a Beckman 406 analog-to-digital convertor (ADC), whose output can be collected by the chromatographic software. In their set-up, the P/ACE™ 5000 CE unit was used to control all CE functions such as capillary rinses and injection and separation parameters and in addition, it was

used for data collection and chromatographic integration, reporting, and plotting functions. The maximum detector output was matched to the 2-V input limit of the ADC using a simple voltage divider circuit. A block diagram of the main instrument components is shown in Figure 3.

The image size produced by the aspheric condenser lens was evaluated for proper matching of the image size to the photodiode active surface area. The experimentally determined mean diameter is 0.575 mm, indicated a slight overfilling of the 0.5-mm detector window. The rapid change in signal upon minor detector position was a good indication of an acceptable image size match. A three-dimensional representation of the image produced by the aspheric condenser lens is shown in Figure 4.

The sensitivity of the system was evaluated by injecting serial dilutions of the labeling dye NN382 (40). \( \lambda_{\text{abs}} = 776 \text{ nm}, \lambda_{\text{em}} = 796 \text{ nm}, \text{H}_2\text{O} \) which is suitable for use with the systems excitation and detection wavelengths (Figure 5). A linear detector response \( (r = 0.9999) \) was observed over more than a 250-fold concentration range between \( 1.4 \times 10^{-9} \) and \( 5.5 \times 10^{-12} \text{ M} \) (Figure 6). A SNR, signal/root mean square noise) of 15 was observed for a 70-nL injection of the \( 5.5 \times 10^{-12} \text{ M} \) solution, which indicated a limit of detection (SNR = 3) of approximately 80 zmol. The electropherogram of a 70-nL injection of the 5.5 pM solution (385 zmol injected) is provided in Figure 7.

The sensitivities obtained were under 100% aqueous conditions, and additional improvements could be expected with the use of organic modifiers, cyclodextrins, or micellar additives above their critical micelle concentration in the run buffer, from an improved fluorescence quantum yield when the dye is exposed to a more hydrophobic environment. Comparison of the photophysical properties of the dye in methanol suggested that a fourfold improvement in signal could be obtained when using the dye NN382 in a more hydrophobic run buffer, containing a cosolvent such as methanol. Additional improvements in detection sensitivity could be attained using an NIRD with an emission wavelength better matched to the band-pass filters in the detector. The current system utilizes three 825-nm band-pass filters that significantly attenuate the fluorescence signal emitted at 800 nm. The relative fluorescence signal reaching the detector is only a fraction of the fluorescence produced.

Light collection efficiency and lens and filter transmission efficiency influence the amount of light that will
Figure 4 Three-dimensional representation of the image produced by the aspheric condenser lens.

Figure 5 Absorbance and fluorescence spectra of NN382 (in phosphate buffer, pH 7.2).

actually reach the detector. Thus, the maximum efficiency of the optical path in the experimental set-up can be estimated as follows:

- light collection efficiency of mirror: 10%;
- transmission efficiency of aspheric condenser lens: 98%;
- transmission efficiency of first detector lens: 98%;
- maximum transmission efficiency of each band-pass filter: 70%;
- transmission efficiency of second detector lens: 98%.

The overall result is that only about 3.2% of the fluorescence signal reaches the detector.

The quantum efficiency of the detector (even though relatively high for an APD at 800 nm, ~80%) further reduces the number of photons that actually produce a detector response. The improvement that can be attained when better matching band-pass filters with the dye emission profile, or dye selection with the system band-pass filters, can be estimated. A comparison made between the area of the NN382 (40) emission curve from 810 to 840 nm and the maximum area that could be attained from 781 to 811 nm (±15 nm from the emission maximum) shows that maximum area was 70% larger than the area of the curve corresponding to the band-pass filter wavelengths. Using a dye with an emission wavelength
around 825 nm could therefore result in about a 1.7-fold increase in signal, assuming a comparable fluorescence emission profile. The noise would remain unchanged, suggesting that an additional 1.7-fold improvement in SNR could be attained. All the above-mentioned factors demonstrate important aspects of LIF instrumentation design. To optimize sensitivity, laser excitation should occur below the absorption maximum when a dye has a relatively short Stokes shift. Band-pass filters should be optimized for the fluorescence emission maximum of the dye. This design will effectively attenuate the Rayleigh scatter from the laser while optimizing fluorescence signal collection.

The automated NIRLIF system developed has sensitivity in line with state of the art results obtained by several investigators utilizing highly optimized laboratory-made detection systems. The latter systems utilize high-quality microscope optics for fluorescence emission collection and tightly focused laser excitation beams. Few investigators have reported limits of detection below the zeptomole range. Sub zeptomole detection limits have been achieved using CE by investigators including Soper et al.\textsuperscript{(38)} (0.4 zmol) and Dovichi et al.\textsuperscript{(33)} (0.050 zmol). Impressive sensitivities as low as single-molecule detection have also been reported for molecules in a flowing stream, demonstrating the possibilities of LIF when used with CE.\textsuperscript{(42,43)} In order to attain these sub zeptomole levels, an off-column sheath-flow detection arrangement was generally utilized to reduce the amount of background scatter. Neat dye solutions were used under conditions that optimized the quantum yield of the dye (Φ), not necessarily desirable for real CE applications. High laser powers, time gating and data smoothing have also been utilized to achieve these results.

The data presented here are for an NIR labeling dye used under 100% aqueous conditions in a fully automated instrument, suitable for routine use. Additional improvements in sensitivity could be achieved by increasing laser excitation power, improving the dye fluorescence quantum yield, and optimizing the dye emission profile with the band-pass filters. The NIRLIF system uses more compact, rugged, and less expensive components with an expected lifetime of >100,000 h. The fully automated injection, separation, and data collection capabilities of the commercial CE system were preserved.\textsuperscript{(28)}

The fully automated system developed was then used to evaluate the suitability of the NIRD NN382 (40) as a peptide labeling agent. Six angiotensin-I (Ang-I) variants were selected as model peptides for derivatization and separation studies.\textsuperscript{(44)} The calculated charge-to-mass ratios of the derivatives and excess dye (at pH 7.2) are given in Table 7, listed in expected order of elution in a normal polarity CZE separation. The smallest charge-to-mass ratio difference is between the human and Val-5 forms, where the substitution of valine for isoleucine
represents a difference of a single methyl group for the 2295 (formula weight) labeled peptide.

The closely related decapetides were labeled with the NIRD, separated using CE, and detected by NLRIF. Derivatization of the peptides was achieved under aqueous conditions using 2.5–500 pmol of Ang-I in a 50-µL sample (5 x 10^-8–1 x 10^-5 M). The fluorescence response was linear over a 200-fold range (r > 0.9986) and the SNR of a 1.3-amol injection of the Ang-I variants was >15, indicating a limit of detection (SNR = 3) of <240 zmol. Four of six peptides were resolved from each other and excess dye using CZE. Two pairs of co-eluting peptides were successfully resolved using MEKC. Two neutral NIRDs were identified as suitable markers for measuring electroosmotic and micellar flow.  

Another application evaluated with the NLRIF system was in CGE. The suitability of NLRIF detection with CGE was investigated. The purity of NIR-labeled primers was assessed, and detection linearity and sensitivity using CZE were evaluated. Slab gel electrophoresis has been used for many years for the analysis of proteins, oligonucleotides, DNA, and other biomolecules. The applications of this technique are very powerful and widespread, but also slow, labor intensive and prone to poor reproducibility.  

CGE was developed to automate and simplify traditional gel electrophoresis methods. The advantages of using CGE include the ability to automate the process fully, provide on-line quantitative detection, and use smaller sample amounts. The capillaries are superior at dissipating heat, allowing the use of higher voltages, resulting in improved efficiencies and shorter run times.

LIF detection has been successfully applied to DNA sequencing methods. Swerdlow et al. reported sequencing rates of up to 1000 bases per hour using fluorescent-labeled primers. Another scheme uses fluorescent intercalating dyes, such as those marketed by Beckman, for the analysis of ds DNA with LIF detection. Although the total sample throughput is still limited using CE compared with slab gel methods, this limitation is likely to be overcome. Through the use of one-channel, four-dye detection schemes and the development of multicapillary instruments, this limitation can be overcome. Beckman has recently introduced an eight-capillary CE instrument for DNA analysis and Ueno and Yeung reported on the use of a 100 capillary bundle.

CGE with LIF detection was utilized to assess the purity of NIR-labeled oligonucleotides. The CGE method showed great sensitivity, with limits of detection around 90 zmol and a 1000-fold linear dynamic range. The number of theoretical plates obtained for the primers exceeded 300 000. The excellent sensitivity and high separation efficiency observed for the NIR-labeled primers indicate their suitability for many other CGE applications. Sensitivity results are comparable to those reported by Williams and Soper for a similar NIR-labeled primer. The excellent sensitivity and separation efficiencies obtained for the NIR-labeled primers suggest they may be suitable for many of the other CGE applications described earlier.

The use of fluorescent-labeled primers in binding studies of synthetic oligonucleotides, such as antisense therapeutics, has been demonstrated. Vilenchik et al. monitored the hybridization of a phosphorothioate target with a complementary labeled DNA probe. Protein to DNA binding studies were shown by Xian et al. using a CE mobility shift assay with CGE. An assay to determine the activity of a transcription factor (SpP3A2), obtained from the nuclei of a single sea urchin egg, was based on the difference in mobility of a free or bound fluorescent labeled DNA probe.

4.2.2 Application of Near-infrared Fluorescence in Immunoassays

IA is a method of analysis that relies on specific interactions between an Ab and an antigen (Ag) to measure a variety of substances, ranging from complex viruses and microorganisms to simple pesticide molecules and industrial pollutants. To observe and measure this reaction, a label is introduced via a second Ab. Conventionally, this label consists of a radioactive isotope (radioimmunoassay (RIA)), an enzyme (enzyme-linked immunosorbent assay (ELISA)) or a fluorescent molecule (fluorescence immunoassay (FIA)). The use of Abs as analytical regents was first reported in 1959 when Berson and Yalow successfully demonstrated the measurement of picogram levels of human insulin in samples of body
fluorescence in IAs. The use of LIF in IAs has been shown to provide an alternative to improve the sensitivity of detection. Limiting the detection to about 10^6 molecules L^-1 reagents and scattering and quenching effects of solvents, from the biological samples' autofluorescence or sample preparation conditions can result in high background interference, in addition to the previously discussed interference, in the determination of conventional assays. An RIA for the insecticides aldrin and dieldrin was the first reported IA for an environmental contaminant. Although a few RIAs still exist in the medical field, they are seldom used in environmental and food analysis because of the need for special handling and disposal of the radioactive materials. Radiolabels were gradually replaced with enzyme labels owing to the hazards associated with radioactive materials. ELISA, which was first introduced by Engvall and Perlman in 1971, has become perhaps the most popular IA format used in laboratories today. The modern diagnosis of many diseases, especially infectious diseases, is almost completely dependent on these assays. In diseases of global importance such as acquired immunodeficiency syndrome (AIDS), cysticercosis, malaria, filariasis, and schistosomiasis, IAs play a key role in screening and diagnosis.

Utilizing the advantages of fluorescence over absorbance, conventional fluorophores can be theoretically capable of detecting fewer than 10^6 molecules L^-1 in conjunction with the highly specific activity provided by IAs. However, in practice, the high background from the biological samples' autofluorescence, or sample reagents and scattering and quenching effects of solvents, limit the detection to about 10^-10 molecules L^-1. LIF provides an alternative to improve the sensitivity of fluorescence in IAs. The use of LIF in IAs has been reviewed. The limitations of conventional lasers as excitation sources are their high price, size, maintenance costs and their limited wavelength selection. LIF in the NIR region (600–1100 nm) offers several advantages. Recent advances in semiconductor laser technology have made the use of lasers more practical. The widespread use of NIR-emitting laser diodes in the telecommunications industry has made them more readily available. This type of laser is inexpensive (typically < $150) and small (~1 cm) and has a much longer operating lifetime (> 100 000 h).

The GaAlAs laser diode has drawn much interest because its emission wavelength of approximately 800 nm is compatible with several classes of polymethine cyanine dyes, which exhibit NIR fluorescence. Detection in the NIR region allows one to replace commonly used photodiodes by APD. The APDs have excellent quantum efficiency in the NIR region. Some of the advantages of APDs are that they are much cheaper, more compact, and longer lasting. In addition, they have low internal noise and very low power consumption. All these features make the NIR fluorescence IA highly amenable to miniaturization and can aid in the development of a portable, compact and rugged instrument for field application.

Heptamethine cyanine dyes are a class of NIR fluorophores that have been used for DNA sequencing, pH and hydrophobicity determination, metal ion detection, and Ab labeling. They are ideal for labeling Abs involving conjugation chemistry, e.g. the reaction of the isothiocyanato group (NCS) on the NIRD with the primary amine groups on Abs. These dyes have high molar absorptivities (ca. 10^5 L mol^-1 cm^-1), high quantum yields (20–40%), relatively short fluorescence lifetimes (500–1000 ps), and are small (~1000 Da). The small size of these dyes in comparison with the target molecule allows for a high number of labels per Ab without compromising Ag/Ab interactions. This implies higher selectivity and signal coupled with low background interference, in addition to the previously discussed advantages offered by the NIR region. Additionally, the use of a solid matrix generates a stronger signal by concentrating the fluorescent molecules and thereby reducing quenching effects of the solvent.

Boyer et al. were the first to demonstrate the feasibility using diode laser detection in the NIR region. They compared the efficacy of the NIR assay method with the conventional ELISA method. Williams constructed an NIR fluorescence detector for detecting fluorescence in an IA format. The set-up developed is illustrated in Figure 8. The instrumentation comprised an excitation source coupled with a fiber-optic cable, a silicon photodiode as detector, a sample-holding apparatus that could be adapted to hold various forms of solid support matrices coupled with a motor drive, and a data acquisition interface. The instrument could detect concentrations of 100 pmol of NIRDs. Using this set-up, the near-infrared

![Figure 8 Block diagram of NIR fluorescence detector.](image-url)
fluorescence immunoassay (NIRFIA) on a nitrocellulose matrix was capable of detecting $5 \times 10^{-10}$ M human immunoglobulin G (IgG). The overall assay could be performed in less than 2.5 h in the absence of the substrate development step which is employed in the conventional ELISA method. This NIRFIA allowed the detection of approximately 47,000 labeled Ab molecules.

This method developed, however, had its disadvantages. A high degree of scatter generated by the membrane, problems with nonspecific binding of the conjugate, and its lack of compatibility with the most common format of modern IAs, the microtiter plate assay format, limit its practical use. In continuation of the development of solid-phase NIRFIA, the above-mentioned issues and others were addressed in a study by Swamy. An NIRFIA was developed based on the heptamethine cyanine dye NN382 (40). The dye used in this study had a high molar absorptivity ($\varepsilon = 180,000 \text{ L mol}^{-1} \text{ cm}^{-1}$) and quantum yield ($\Phi = 0.59$, for dye–Ab conjugate). The isothiocyanate functionality reacts selectively with the amino group of the Abs to form a stable thiourea bond. The presence of the sulfonated groups makes the dye highly water soluble, making it ideal for labeling Abs. Another advantage of the negatively charged sulfonate groups on the dye is that it minimizes nonspecific binding to the solid matrix (polystyrene (PS)).

A solid-phase NIRFIA was systematically developed in the following steps. A LI-COR 4200 prototype fluorescence microscope was coupled with an orthogonal scanner and was evaluated for optimum depth of view. Next, the optimum scanner operating conditions were determined in terms of gain, offset, and scan speeds to optimize settings for maximum dynamic range and SNR and ensure reproducible scans. Appropriate modifications to the mounting of the scanner microscope and scanning platform were made to allow the examination of microtiter plates (Figure 9). The linear response of the detector was verified with increasing gain for a given voltage setting. A number of microtiter plates (solid matrix) were then evaluated in order to provide the one with minimum background noise. Once the reader had been configured and the solid support had been augmented, the procedure for covalent conjugation of NIRD NN 382 (40) to goat antihuman immunoglobulin G (GAHG) was systematically optimized in terms of pH, temperature, time of reaction, and reactant molar ratio. The conditions that provided the maximum results were a pH of 10, an initial dye:Ab ratio of 1:125, a temperature of 25°C and a coupling time of 1 h. These conditions are all critical parameters since any deviation results in under- or overlabeling of the Ab, which, in turn, results in a low specific activity and detection ability. The absolute concentration of reactants was found to be critical for the rate of the coupling reactions; therefore, in the optimization procedure, stock solutions of dye (10 mg mL$^{-1}$) and Ab (1–3 mg mL$^{-1}$) concentrations were used. Although the conditions for coupling other species of Ab were not optimized, other conjugates were successfully prepared with high specific activity. The optimum conjugation procedure was defined by the conditions that produced an NIRD-labeled Ab with the highest specific activity in an immunosorbent assay for normal human immunoglobulin G (NHIgG). The best conjugate was used to determine detection limits for the assay and was able to detect $2 \times 10^{-11}$ M of NHIgG. This provided a sensitivity about 10 times greater than that achieved by conventional labels in similar assays. Finally, the assay was validated by 100% agreement with clinically diagnosed samples for schistosomiasis and its cross-reactors.
One major disadvantage of this method is the lack of commercial instrumentation for the assay. Quantification of the signal obtained in an image format is problematic. However, commercial software for quantifying on line signals from DNA sequences in the NIR region is available (LI-COR). Adaptation of similar software for microtiter plate scans would be immensely helpful. The method developed does have many advantages over conventional methods and the versatile nature of the scan bed does not limit this assay to the microtiter format. Technically, the scanner could scan any matrix, limited only by the physical dimensions of the scanner (ca. 23 cm and 61 cm long). This could allow for scanning multiple assays and 500–1000-well plates. The assay is very quick, requiring less than 20 min for the assay itself, and requires fewer steps than ELISA. The ability to detect lower concentrations of Abs would help in earlier diagnosis and an opportunity to test drugs against opportunistic infectious agents at an earlier stage. The labeling of Abs with NIRDs provides an important advancement to IAs and the comparatively small size of the NIRD allows for a higher molar ratio of NIRD per Ab. This in turn yields a higher signal and allows for lower detection limits. The assay has also been validated for clinical samples and could be further evaluated in the development of a diagnostic test.

In principle, various bioanalytical methods can be developed using the NIR immunochemistry described in the preceding section. To demonstrate the versatility of the method, Swamy et al. developed two bioanalytical applications utilizing NIRFIA in collaboration with the State University of New York (SUNY) at Brooklyn and the Department of Entomology and Environment Toxicology at the University of California, Davis, CA, USA. The first application involved an NIR-labeled Ab in the detection of extracellular Ag expressed on cells. This demonstrated the feasibility of using NIR-labeled Abs in clinical imaging applications such as NIR optical tomography. The second application uses the NIRFIA as an analytical tool in environmental applications in the quantitative analysis of two pesticides, bromacil and fenvalerate.

In the evaluation of the NIRD-labeled Ab for imaging applications, the NIRD NN82 was coupled to monoclonal Ab E48 (MAb E48) and the conjugate was evaluated in a direct assay to detect a 22-kD Ag expressed on the surface of human squamous cell carcinoma line (HuSCC) A431. The specificity of binding was confirmed in a competitive assay. The preliminary results showed good sensitivity and specificity of the NIRD-labeled Ab. In the environmental application, the assay was evaluated in a rapid tracer format competitive assay for the detection of the pesticides bromacil and pyrethroid. In this assay, the specific Ab captured on the surface of microtiter plate well and the tracer with fluorescent label compete with the analyte for the Ab. The results obtained showed that the NIRFIA was at least as sensitive as ELISA, with both assays detecting pesticides in the micrograms per liter (parts per billion) range. (2)

The chemistry and the instrumentation of the NIRFIA technique for environmental applications have been developed, but are amenable to further miniaturization. Further optimizations would allow for the future construction of compact instrumentation for analysis which could conduct fast and reliable assays at remote locations. In continuation of this approach, preliminary results obtained in our laboratory demonstrated the feasibility of using the NIRFIA approach for an NIR/fiber optic immunoassay (FOI). This approach is particularly useful for measuring small amounts of analyte and can be automated and carried out in remote locations. Several fluorescent immunosensors have been reported; however, lack of commercial instrumentation and labels limit the use of these techniques and most applications utilize UV/VIS dyes. The applications of the visible fluorescent immunosensors described are all susceptible to interference from biomolecules such as bilirubin and porphyrins. A comprehensive review of immunosensors has been published by Robinson et al. (66) Danesvar (67) developed a NIR/FOI for detection of trace amounts of human IgG and Legionella pneumophila. They optimized the assay on different solid phases such as poly(methyl methacrylate) (PMMA) and PS. The PS coating method eliminated the activation process required with PMMA, thereby reducing the preparation time by 18 h; in addition, it also eliminated the protein G step of the previous assay. The assay was carried out in a sandwich format (Figure 10). The set-up used to measure the signal (Figure 11) allowed concentrations of 10–11 M for IgG (SD = 0.13) and 0.5 ng mL−1 for Legionella pneumophila sera type 1 (LPS1)67 to be detected. These results were comparable to those attained by conventional ELISA. Another application using a similar format was developed by Evans (68) and provided a competitive assay for the pesticide bromacil. A detection limit of 5 ppb was obtained, which was slightly higher than that reported for ELISA (0.1 ppb). However, the method had advantages since it did not require extensive sample preparation, the assay time was substantially reduced, and the assay could be adapted for remote site analysis. (68)

The NIR/FOI technique in principle is a flexible methodology, which can be theoretically adapted to develop assays for any compound for which Abs are available, including infectious agents, serum analytes, and environmental pollutants. This technique provides a real-time analysis with automated readout capabilities, eliminating the need for operator intervention or
complicated sample preparation. Although the detection optics for the assay were originally constructed on a 2 × 3 ft optical table, the set-up can be reduced in size. The preliminary sensitivity, selectivity, and simplicity of the assay are encouraging and further design refinement and other applications should aid the development of versatile NIR/FFOI.

4.2.3 Application of Near-infrared Fluorescence in High-performance Liquid Chromatography

Another bioanalytical application developed using the advantages of NIR fluorescence is HPLC detectors. In recent years, the ability to measure ultralow levels of pharmaceuticals in biological matrices has presented significant challenges. Using fluorescence as a tool for detection, sensitivities of picograms per milliliter have been achieved. Rahavendran and Karnes have described the advantages of LIF detection in HPLC. There have not been many publications dealing directly with HPLC detection in the NIR region. Until recently, two groups worked on the development of applications of NIR fluorescence in HPLC, Winefordner’s group at the University of Florida and Ishibashi’s group in Fukuoka, Japan.

One of the first NIR fluorescence-based HPLC detectors was developed by Ishibashi’s group. They detected 0.3 pg of a carbocyanine dye with instrumentation comprising a 3-mW diode laser emitting at 780 nm with a PMT cooled to −20 °C for detection. They reported a detection limit of 1.9 pg at room temperature. Sternberg et al. of Beckman Instruments used a 2.5-mW diode laser coupled with a commercial diode-array detector and achieved a detection limit of approximately 10−10 M for a carboxyl cyanine-labeled oligonucleotide. Winefordner et al. explored the detection of cyanine dyes in different instrumental configurations using a diode laser for excitation with a PMT for detection. They achieved detection of 46,000 molecules in a liquid jet fluorescence spectrometer. Karnes et al. used diode laser-induced NIR fluorescence for detection of ICG in plasma. They demonstrated a detectability of more than two orders of magnitude over absorbance.

Another NIR HPLC application was reported by Kuklenyik, who developed and compared two detectors for NIR fluorescence detection based on a...
silicone photodiode and an APD. The merits of this type of detector were also compared with those of conventional PMT detectors. An HPLC system (SSI gradient system) with a high-pressure pump capable of providing 500 psi pressure controlled by an IBM computer was coupled with an in-house developed excitation and detection system. The experimental set-up of the excitation and detection and the final set-up are shown in Figures 12 and 13. It comprised a silicon photodiode detector coupled with a 24-µL HPLC flow cell shown in Figure 12 and, in the set-up with an APD, a modified Model 4200 LI-COR microscope was used instead of the silicon photodiode. Detector performance was evaluated with two NIRDs, IRD40\textsuperscript{W} (41) and 1,1′,3,3′,3′-hexamethyl-4,4′,5,5′-dibenzimidotricarbocyanine perchlorate (42), first without an HPLC column followed by subsequent runs with C\textsubscript{18} HPLC columns. Detector signals for three consecutive injections of IRD40\textsuperscript{W} at 10\textsuperscript{-10} M concentration are shown in Figure 14. Detection limits of 1.22 × 10\textsuperscript{-11} and 5.89 × 10\textsuperscript{-12} M were achieved for the two dyes and the numbers of dye molecules detected were calculated to be 36 500 and 17 600, respectively.\textsuperscript{74} The overall results showed that the less expensive, more efficient photodiode was sensitive for detection in the NIR region. The detector was designed to collect signals at 820 nm, and a better match of the dye emission with the detector and better light collection efficiency should help improve the sensitivity much more. Even in the early stage of development in this direction, the NIR fluorescence method shows sensitivity comparable to or better than those of conventional methods. Further evaluations and modifications could help achieve much greater sensitivities.

4.3 Environmental Applications of Near-infrared Fluorescence

The fundamental principle involving the analytical applications of dyes to study the microenvironment essentially involves the changes induced by the analyte that can be directly measured by spectral changes. These changes depend on the concentration of the analyte and the interaction between the analyte of interest and the dye. Typically these probes involve a cation-selective receptor either as an integral part of the chromophore’s π-system or covalently attached to the fluorophore via an alkyl tether.\textsuperscript{75–77} The coordination of the cation affects the spectral position of absorption and emission bands, molar absorptivity, and, to a smaller extent, the fluorescence quantum yield. The interaction of a metal ion with an organic reagent might result in the enhancement of the fluorescence or the quenching of the fluorescence of the organic reagent in the presence of an analyte. A statistical study showed that about 89% of luminescent methods are based on the enhancement of fluorescence and about 11% are based on quenching reactions.
The investigation of toxic metal ions in the environment has been of growing interest in the past few decades and the decreasing permissible limits for most of these metal ions set by major health organizations such as the World Health Organization (WHO) and the United States Environmental Protection Agency (USEPA) have provided a tremendous thrust for the development of sensitive analytical techniques. Most of the publications devoted to the detection of metal ions by means of spectroscopic techniques used UV/VIS probe molecules such as rhodamine, fluorescein, 8-hydroxyquinoline, and their derivatives.\(^{78-83}\) Table 8 provides a list of some of the different fluorescent sensors that have been used for the determination of the most commonly studied metal ions, namely Al(III), Be(II), Co(II), Fe(III), and Li\(^+\). Unfortunately, spectral interference is significant in this region. The use of NIRDs is a better alternative.\(^{84-90}\)

The low background interference observed for other molecules in the NIR spectral region together with the longer Raman shift offers better SNRs. Casay et al.\(^{91}\) investigated tetrasubstituted NPc NIRDs as potential probes for the determination of toxic metal ions. They developed the first NIR optical probe that could detect lead, lithium, and cadmium at parts per billion levels.\(^{91}\) More recently, Tarazi\(^{93}\) reported the detection of metal ions using three novel NIRDs, namely TG 170 (43), NN525 (44), and JCM-15C5 (45). The spectral characteristics of the three dyes are listed in Tables 9–11. They evaluated TG 170 for the detection of Al(III) and Be(II), NN525 for the detection of Fe(III) and Co(II) ions, and JCM-15C5 for the detection of Li\(^+\) in the presence of other interfering ions.

\(^a\) E = enhancement of fluorescence; Q = quenching of fluorescence.
The hydroxy carboxy functionality of TG 170 (43) has a known selective complexation with Al(II) and Be(II) ions. Using this dye, they reported a detection limit of 52 ppb for Al(III) and 24.6 ppb for Be(II) ion. For the NIRD NN525 (44), only Fe(II), Fe(III), and Co(II) ions resulted in quenching of fluorescence. Detection limits of 3.54 ppb for Fe(III) and 1.55 ppb for Co(II) were obtained. The calibration curves obtained for the two metal ions are illustrated in Figures 15 and 16. The crown ether functionalized cyanine dye JCM-15C5 (45) was used for detection of Li$^+$ ions in the presence of other interfering ions. They obtained a linear plot of fluorescence intensity for Li$^+$ amounts ranging from 0.0347 to 0.222 ppb (Figure 17). A detection limit of 0.0743 ppb was reported. The stability constant for the JCM-15C5 complex was higher than those achieved in other studies. The method development represents a significant improvement over conventional methods. Owing to the minimal interferences encountered in the NIR region, it eliminates the need for extensive sample preparation, and additionally it allows for the development of tests that can be carried out at remote sites by rugged compact instrumentation.

Another novel application developed with NIRDs for the detection of Ca$^{2+}$ was reported by Akkaya and Turkyilmaz.94 They developed a squaraine-based fluorescent sensor for calcium [Scheme 6, (47)]. The probe developed was very sensitive to Ca$^{2+}$ concentrations in the
The use of an inexpensive commercial laser diode emitting at 690 nm for excitation and a photodiode for detection, opening avenues for the development of compact, rugged systems free from background interferences for cellular ion-flux studies and real-time imaging applications.

Another unique environmental application developed was an NIR phase-resolved fluorescence spectroscopy-based fiber-optic corrosion sensor for the detection of aluminum and iron and their corrosion by-products by Chin et al. The method essentially involves an NIRD that is embedded in a fiber-optic cladding, coupled with appropriate excitation and detectors and integrated with an in-house phase-resolved fluorescence spectroscopy board. A block diagram of the set-up is shown in Figure 19. They studied three in-house synthesized NIRDs, TG1, TG2, and TG3 for complexing Al(III) ions. The method was more effective than conventional fluorescence techniques because it measures the lifetime changes of the dye which are independent of the surrounding environment as opposed to fluorescence. Table 12 lists the fluorescence lifetimes for the three dyes in the presence of Al(III) ions. This method developed was very versatile as it could be integrated into airframe and wings of aircraft or other critical failure locations (fasteners, bolts, composite joints, welds) for measuring corrosion. Thereby, strain and structural fatigue can be monitored using NIR technology. The preliminary results obtained were very encouraging and future potential uses of this system could include monitoring composite life cycles and corrosion and structural fatigue of launch pads, rockets, space structures, and advanced aircraft.

4.4 Other Applications of Near-infrared Fluorescence

In this section, we describe other analytical applications developed with NIR fluorescence. The first application discussed is the determination of hydrogen ion concentration (pH), which is an important part of many

analytical procedures. The use of fluorescent dyes and indicators for pH measurement is well documented in the literature. A number of indicators with spectral characteristics in the UV/VIS region have been reported, but only a few have been reported for pH measurements in the NIR region. Several classes of NIR pH-sensitive dyes have been developed in our laboratories at Georgia State University in collaboration with Strekowski et al.

Of these pH-sensitive dyes, the most useful include the bis(aminodiene)ones that undergo transformation from the keto form to the cyanine enol form. A pH-sensitive dye (51) (Scheme 7) showed distinct bands under acidic and basic conditions (Figure 20). The absorbance maximum at 531 nm undergoes a strong bathochromic shift in acidic conditions with a concomitant change in fluorescence spectra with an absorbance band at 709 nm. The change in absorbance maximum is attributed to protonation of the oxygen atom which induces a shift to the cationic enol form of the dye and restores the cyanine chromophore to give a bathochromatic shift to the NIR region. Another pH-sensitive NIRD (53) was evaluated.

Scheme 8 Novel pH-sensitive NIR ethoxy adduct of IR-1048 (54).

Mason et al.\textsuperscript{105} recently prepared a number of C2-derivatized indolenine NIR chromophores that exhibit unique spectral properties as a function of pH. Of this series, JCM-1048-OEt (54) (Scheme 8) was studied by Tarazi.\textsuperscript{93} The molecular structure of the dye contains an ethoxy moiety covalently linked to the C2-position of the 3\(H\)-indole. This addition results in the interference of the cationic delocalization that is typical of cyanine dyes and produces a complex absorption spectrum with a \(\lambda_{\max}\) at 511 nm. However, addition of acid regenerates the cationic chromophore IR-1048 (55) to give a dramatic red shift to 1050 nm. The spectral characteristics of the dye in different pHs are shown in Figure 22. As can be seen, the dye exhibits two characteristic absorptions, one in the NIR and the other in the UV/VIS region. The dye exhibited a linear range for the NIR peak over the pH range 6–9 in acetone, pH 5–9 in acetonitrile and pH 6–12.
in water as the solvent. In addition to the C2-derivatized NIRD, Mason et al.\cite{106} reported the synthesis of a bis(aminodiene)one, JCM-648/932 (56) (Scheme 9) that exhibits pH-dependent absorptions in the NIR region. In neutral or basic conditions the equilibrium favors the keto form with an absorbance maximum of 648 nm in methanol. However, addition of acid results in the protonation of the carbonyl to restore the cyanine system. This acidic species (57) shows electronic absorption at 932 nm. The transformation from the keto to the enol form is fully reversible and can be carried out repeatedly.

Another application developed using NIR fluorophores is fluorescence detected circular dichroism (FDCD). This method is similar to absorption CD, but fluorescence intensity as opposed to absorbance is the measure of molecular ellipticity. Absorption CD is a valuable tool for examining the molecular chirality of proteins in the ground state. However, owing to the limited number of chiral centers, CD is often limited to qualitative measurements and global conformational changes instead of optical activity about specific centers. Tinoco and Turner reported the ability to circumvent conventional problems with CD measurements by the FDCD technique.\cite{107,108} FDCD can be used to measure the CD of a single contributing chiral fluorophore while avoiding nonfluorescent chiral absorbers and achiral fluorophores.\cite{108,109} For example, fluorescence from a single tryptophan residue has been measured in the midst of other chiral absorbing residues present in proteins. Structural studies of proteins with and without ligand binding have also been reported.\cite{100–112}

Similarly to fluorescence spectroscopy, FDCD makes use of a 90° angle relative to the excitation source for detecting the fluorescence. Unlike fluorescence, where plane polarized light is used for excitation, circularly polarized light is used in FDCD. When in the absence of energy transfer and only a single chiral fluorophore exists at the analytical wavelength, the detected FDCD is for a particular population of fluorophores. This situation may be inconceivable in many applications where many proteins may be present in a mixture. In order to avoid complications with matrix interferences, chromatographic techniques have been used in conjunction with FDCD.

Yeung et al.\cite{113,114} reported the use of LIF with FDCD coupled to HPLC and CE. They reported detection limits of 170 and 0.07 pg for riboflavin by HPLC/FDCD and CE/FDCD, respectively. Thomas et al. reported the use of multidimensional FDCD for resolving mixtures without physical separation\cite{111,112}. This method utilized the differences in the excitation and emission bands for resolving the fluorescence spectra of optically active fluorophores. Resolving mixtures of optically active fluorophores based on their fluorescence lifetimes has also been reported.\cite{115,116} Since CD is a weighted-average measurement,\cite{115} many chromophores present in biomolecules contribute to the CD signals. This presents a quantitative limitation in CD measurements. Although the same rules apply to FDCD, intrinsic fluorescence from optically active fluorophores limits the measured CD to a few possible molecules such as tryptophan, tyrosine, and phenylalanine in proteins. However, when chiral nonfluorescent molecules absorb in the ultraviolet (UV) region, the radiation intensity incident on the fluorophore of interest can be weakened. Consequently, the emission intensity may diminish. Considering the lower quantum yields associated with fluorescent protein residues and the number of potential interfering transitions, CD and FDCD at shorter wavelengths are limited.

Long-wavelength alternatives to UV CD measurements have been reported. Keiderling discussed the use of vibrational circular dichroism (VCD), a chiroptical
analog of IR spectroscopy. This technique measures the intrinsic vibrational modes of proteins which avoids some of the limitations of conventional absorbance CD. Sophianopoulos et al. used extrinsic NIR chromophores as structural probes in near-infrared circular dichroism (NIRCD) measurements. Since synthetic probes possessing various properties are readily available, photophysical limitations of intrinsic chromophores can be avoided. Although VCD and NIRCD have the advantage of avoiding biological background interferences, they lack the sensitivity gained in FDCD.

Since there are very few proteins that exhibit long wavelength fluorescence, greater sensitivity, selectivity, and spectral resolution can be gained through the use of near-infrared fluorescence-detected circular dichroism (NIRFDCD) of extrinsic fluorophores. Many biomolecules typically absorb only at lower wavelengths, and thereby complex samples can be potentially analyzed without physically separating matrix components. Typically, NIRDs are optically inactive, low molecular weight (MW \approx 1000 \text{ g mol}^{-1}) symmetrical compounds that do not yield FDCD. When placed in an asymmetrically perturbed environment, as in protein binding sites, chirality may be induced, resulting in Cotton effects. Therefore, these compounds must meet two criteria in order to exhibit FDCD: first, the molecule must be fluorescent in the NIR region, and second, it must possess induced chirality through noncovalent interactions with the macromolecule clearly indicating that binding has occurred. In our laboratories NIRFDCD was used in order to gain a better understanding of the structure of NIRDs that bind proteins. An understanding of dye binding to albumin may relay important information concerning these dyes as labels or probes in analytical techniques such as the separation of proteins with HPLC, gel permeation chromatography (GPC) or in gel electrophoresis. Meadows et al. recently investigated the NIR squarylium dye NN525 as a non-covalent probe for protein structural determinations. This dye, owing to its rigid squarate residue, has greater photostability relative to its cyanine counterpart. They found that it forms a stable complex with serum albumins with binding constant in excess of \(10^6 \text{ L mol}^{-1}\) compared with \(10^5 \text{ L mol}^{-1}\) for many other conventional dyes. This in turn added to the ease of detection. Also, the high quantum yield and molar absorptivity permit the use of smaller amounts of dye relative to visible counterparts. Preliminary results showed that NIRFDCD of squarylium fluorophores can be measured using 10–100-fold lower dye concentrations in comparison with normal absorbance CD. The advantage of using lower concentrations of dyes simplifies the assessment of competing equilibria associated with high concentrations such as dye or protein aggregation.

Dye aggregation may in some instances result in the absorption of circularly polarized light. A common finding for many of the NIRDs previously studied is the enhancement of photophysical properties upon binding to hydrophobic environments (Figure 23). An increase in these properties permits the use of even lower probe concentrations. This can be advantageous since lower ratios of bound fluorophores can leave proteins virtually unperturbed structurally.

Previous reports by Sophianopoulos et al. support the binding of NIR squarylium compounds to similar, if not identical, binding sites on bovine serum albumin (BSA) with measurable conformational changes. Many of the symmetrical NIR compounds do not have measurable optical activity in the protein-unbound state. When these dyes bind in asymmetric binding sites of proteins, induced Cotton effects can occur. As can be seen in Figure 24, the relative FDCD intensities found for the three different albumin–dye complexes is in accordance with the absorbance spectra. This indicates
that those transitions occur through asymmetric perturbations in the fluorophore. Structural differences in the binding sites occupied by NN525 cause intensities to differ. Although not confirmed, previous data supported a common binding site near positively charged amino acid residues.\(^{118}\) Homology in this site among different species may account for the common negative Cotton effects observed for different albumins. Differences in the hydrophobities and/or electrostatic interactions at these sites may explain the intensity variations exhibited for the different species. Changes in the extent of the association or weak induced chirality can result from weaker noncovalent interactions. The squarylium dyes had large molar ellipticities (\(10^5 \text{°} \text{cm}^2 \text{dmol}^{-1}\)) when bound to BSA. Although induced CD may occur with binding to macromolecules, optical activity due to intramolecular forces, such as dye aggregation\(^{123,126}\) in aqueous solutions, is less likely at lower concentrations used in FDCD. In many cases these complexes quench fluorescence, but absorb circularly polarized light. Therefore, the CD intensities may falsely indicate asymmetric interactions in the protein-bound dye. The lower concentrations (\(10^{-7} \text{M}\)) needed in these NIRFDCD studies help prevent solubility limitations that can cause the formation of aggregates, avoiding extraneous Cotton effects. Hence the probability of FDCD data containing artifacts from aggregates is small relative to CD. The use of extrinsic fluorophores in NIRFDCD can provide an abundance of complementary information about conformational changes near the fluorophore. The main mode of binding of NIR squarylium dyes to BSA was determined to be hydrophobic, although electrostatic forces may also contribute. Van der Waals contacts near the dye binding site may enhance their association to proteins. The use of CD in conjunction with tryptophan FDCD in proteins and NIRFDCD of noncovalently bound dyes can provide a more detailed description of protein structure and interactions of proteins with ligands. A further advantage of NIRFDCD, the need for lower concentrations, prevents the occurrence of probe and protein intramolecular interactions, which simplifies data interpretation.

5 CONCLUSIONS

The discussions in this article demonstrate the various advantages of working with the novel emerging technology of NIR fluorescence. Reduction in background interference offered by this method is the greatest advantage. No other analytical method known thus far can compete with the highest possible sensitivity achievable, i.e. single-molecule detection, offered by LIF. NIR detection provides advantages in complex biological and environmental systems where background interference is often a major concern. The availability of commercial NIRDs and NIR instrumentation, although limited, has provided a tremendous advance in the development of applications in this region. The commercial dyes or instrumentation can be tailored to specific applications and aid in interfaces with other commercial instrumentation readily available.

The photostability of NIRDs is a cause for concern. However, recent studies have focused on the development of functionalized photostable NIRDs to overcome this problem. The combination of diode laser excitation sources with photodiodes for detection and coupling of these to suitable fiber-optic interfaces aid in miniaturization and allow for development of remote sensing applications. Time-resolved measurements for discrimination between similar species have made the method very useful both in biological applications such as DNA sequencing, cytology, immunoassays, and intracellular measurements and in environmental applications in determining metal ions, pH and microenvironment determination. Other areas that utilize the advantages include photodynamic therapy, thermal transfer printing, optical recording, transparent bar codes, and forgery prevention. Progress continues to be made with more applications being developed using the emerging novel NIR fluorescence technology.

ELECTRONIC ABSORPTION AND LUMINESCENCE

Phosphorescence Measurements, Applications of

Marta E. Díaz García and Rosana Badía
University of Oviedo, Spain

1 Introduction

Phosphorescence emission has been observed from a variety of compounds and is differentiated from fluorescence by the long-lived emission light after cut off of the excitation source. However, the technique has not become a popular analytical method due to problems arising from the practical aspect of measuring the signal at cryogenic temperatures.

Recent developments in RTP have given rise to both fundamental and practical advances which have stimulated interest in phosphorimetry. Solid-surface room temperature phosphorescence (SSRTP) has been generally observed by immobilizing the lumiphor on a solid support such as filter paper or polymeric resins. SSRTP has been shown to be a sensitive and selective approach for the analysis of trace components in biological, pharmaceutical, and environmental samples. Techniques such as SSRTP combined with flow injection analysis provide new avenues for optical sensing transduction and improvement of SSRTP techniques. Applications of SSRTP in flowing systems include the sensing of cations, anions, oxygen, glucose, ethanol, antibiotics, and moisture.

A number of developments in RTP have focused on sensitized phosphorescence (SP) and on the use of ordered media (micelles and cyclodextrins (CDs)), allowing the observation of RTP in fluid solution. In SP the triplet energy of a donor (analyte) is transferred to an acceptor that phosphoresces in fluid solution and the emission of the acceptor is measured. Therefore, SP can only provide quantitative information. In ordered media, a micelle (or a CD) protects the long-lived triplet state from the quenching processes that normally take place in solution, allowing both quantitative and qualitative measurements. SP and ordered media RTP provide the limits of detection for many lumiphors in the nmol⁻¹ range and calibration graphs have a wide linear range.

As new instrumental and basic insights emerge in SSRTP, Micelle Stabilized Room Temperature Phosphorescence (MSRTP), and solution-sensitized RTP, these techniques will find much greater use in the trace and ultra-trace analysis of dissolved, volatile, and gaseous substances in areas such as pharmaceutical analysis, environmental science, and clinical chemistry.

As new instrumental and basic insights emerge in SSRTP, Micelle Stabilized Room Temperature Phosphorescence (MSRTP), and solution-sensitized RTP, these techniques will find much greater use in the trace and ultra-trace analysis of dissolved, volatile, and gaseous substances in areas such as pharmaceutical analysis, environmental science, and clinical chemistry.
studied. The sensitivity of phosphorescence is comparable to that of fluorescence; its selectivity is enhanced through the use of excitation and emission wavelengths and by using time discrimination.

The introduction of microelectronics-based photometers using a pulsed xenon lamp affords easier operation and more sophisticated data treatment using chemometrics.

2 THEORY

2.1 Fluorescence and Phosphorescence

A diagram of the energy levels of a molecule, known as a Jablonski diagram, is shown in Figure 1. Absorption of radiation by a molecule in the lowest vibrational level of the ground state (S₀) results in its excitation to one of the higher energy levels (the lowest, S₁, is called the first excited singlet state). In about 10⁻¹² – 10⁻¹⁴ s, the electronically excited molecule will decay by loss of thermal energy to the lowest vibrational level of the excited states, a nonradiative process known as vibrational relaxation. As the energy gap between excited states is generally small, energy can be transferred from the lowest vibrational levels of S₂ to the highest vibrational levels of S₁. This nonradiative process is known as internal conversion. Eventually, the first excited state (S₁) can be reached by all the excited molecules.

From the lowest vibrational level of S₁, the energy difference to S₀ is usually so great that internal conversion to S₀ has a low probability and is a relatively slow process. In this case, luminescence is observed. Luminescence is the term used for both fluorescence and phosphorescence. In addition to radiative (fluorescence) and nonradiative (internal conversion, vibrational relaxation) pathways, an excited molecule in S₁ can return to the ground state by intersystem crossing to the lowest excited triplet state (T₁). From this level the molecule can again undergo vibrational relaxation to the lowest vibrational level.

The triplet state is lower in energy than the singlet state and a molecule in this triplet state can return to the ground singlet state by different processes, namely emission of radiation (phosphorescence) and nonradiative loss. From a theoretical point of view the main difference between fluorescence and phosphorescence is the nature of the electronic transition involved. Fluorescence is a short-lived emission from the lowest vibrational level of the lowest excited singlet state to the ground state, and does not invoke a change of the electronic spin state. This transition is spin allowed and occurs with a high degree of probability. Phosphorescence involves a change in electronic spin, and thus is called a ‘forbidden’ transition and is highly improbable. As a result, the radiative lifetimes of fluorescence and phosphorescence are very different – for fluorescence it ranges from 10⁻⁹ to 10⁻⁷ s (i.e. the same order as the lifetime of an excited singlet state) and for phosphorescence from 10⁻³ to 10 s. Owing to the relative energies of the excited states, phosphorescence occurs at longer wavelengths than fluorescence.

Given the fact that molecules in the triplet state have long lifetimes, the probability of collisional transfer of energy with other molecules (e.g. solvent molecules) is greatly increased. This process is very efficient in solution at room temperature, being the main pathway for loss of triplet state energy. Phosphorescence requires special experimental conditions under which deactivation processes (intra- and intermolecular) are diminished as much as possible. Fluorescence does not require such special conditions.

A more thorough account of the fundamental radiative and nonradiative processes that are encountered in molecular luminescence spectroscopy is given in standard textbooks and monographs.¹⁻⁷

2.2 Kinetics

Fluorescence and phosphorescence both obey a first-order kinetic rate law; however, the kinetics of the emission as phosphorescence is somewhat more complex than that of fluorescence because an intersystem crossing process to the triplet level is involved.⁸⁻⁹ As only those molecules in the triplet state emit phosphorescence, the emission process may be written as in Equation (1)

\[ T₁ \rightarrow S₀ + hv_p \]  

where \( h \) is Planck’s constant and \( v \) is the phosphorescent wave frequency.
The kinetic rate equation describing the total deactivation of T_1 is given by Equation (2)

$$\text{rate}_p = \frac{d[T_1]}{dt} = -(k_p + k_{st}^i)[T_1] \quad (2)$$

where [T_1] is the concentration of molecules in T_1 at any time, k_p is the first-order rate constant for phosphorescence emission, and k_{st}^i is the rate constant for intersystem crossing (triplet to singlet). The terms k_p and k_{st}^i have the dimensions of time^{-1}. The rate constant k_p is smaller than the corresponding k_i for fluorescence emission and ranges from 0.033 s^{-1} (for aromatic hydrocarbons) to 10^4 s^{-1}. Typical k_i values range from 10^7 s^{-1} to 10^9 s^{-1}. Therefore, phosphorescence is a relatively slow process and the fraction of excited molecules that emit phosphorescence is small; there are nonradiative competing processes which occur at comparable or greater rates than phosphorescence.

For a first-order process, the lifetime \( \tau \) is defined as the time at which the emission intensity has decreased to 1/e (or to 36.8%) of its initial value following termination of excitation, and can be expressed as the reciprocal of its rate constant. Thus, the phosphorescence lifetime is (Equation 3)

$$\tau_p = \frac{1}{k_p} \quad (3)$$

and the observed lifetime of the triplet state is (Equation 4)

$$\tau_1 = \frac{1}{(k_p + k_{st}^i)} \quad (4)$$

The phosphorescence quantum yield \( \Phi_p \) is defined as the ratio of the number of photons emitted to the number absorbed (Equation 5):

$$\Phi_p = \frac{\text{photons emitted as phosphorescence}}{\text{photons absorbed}} \quad (5)$$

In its simplest form, the kinetics definition of \( \Phi_p \) is (Equation 6)

$$\Phi_p = \frac{\text{rate of emission}}{\text{rate of absorption}} = \frac{k_p[T_1]}{k_{abs}} \quad (6)$$

where \( k_{abs} \) is the rate of light absorption. Assuming that no chemical reactions or quenching take place, three processes can deactivate S_1: fluorescence, internal conversion, and intersystem crossing (singlet to triplet), with rate constants \( k_f \), \( k_{ic} \), and \( k_{st}^i \), respectively. So, in the steady state, the rate of absorption equals to the total rate of deactivation of S_1 (Equation 7):

$$k_{deact} = (k_f + k_{ic} + k_{st}^i)[S_1] \quad \text{and} \quad k_{abs} = (k_f + k_{ic} + k_{st}^i)[S_1]. \quad (7)$$

Substituting this value in Equation (6) gives Equation (8):

$$\Phi_p = \frac{k_p[T_1]}{(k_f + k_{ic} + k_{st}^i)[S_1]} \quad (8)$$

In the absence of quenching, there is a loss of absorbed energy through intersystem crossing (triplet to singlet) and, at the steady state, Equation (9) holds:

$$k_{st}^i[S_1] = k_p[T_1] + k_{st}^i[T_1] \quad (9)$$

where \( k_{st}^i \) is the rate constant for intersystem crossing (triplet to singlet).

Now, multiplying the right-hand side of Equation (8) by \( k_{st}^i[S_1]/k_{st}^i[S_1] \) gives Equation (10):

$$\Phi_p = \frac{k_{st}^i[S_1]}{(k_f + k_{ic} + k_{st}^i)[S_1]} \frac{k_p[T_1]}{k_{st}^i[S_1]} \quad (10)$$

Then, substituting Equation (9) and cancellation of \([S_1]\) and \([T_1]\) gives Equation (11),

$$\Phi_p = \frac{k_{st}^i[S_1]}{k_f + k_{ic} + k_{st}^i + k_p} \quad (11)$$

which is the complete kinetic definition of \( \Phi_p \). This expression is the product of the fraction of excited molecules initially in the S_1 state that cross over to the T_1 state (the triplet quantum yield, \( \Phi_T \)) and the fraction of molecules in the T_1 state that emit a photon (the phosphorescence quantum efficiency, \( \theta_p \); Equation 12):

$$\Phi_p = \Phi_T \theta_p \quad (12)$$

2.3 Quenching and the Stern–Volmer Relationship

Another nonradiative pathway of deactivation of an excited singlet or triplet state is quenching.\(^{10-12}\) Luminescence is said to be quenched when the lumiphore and another species (quencher) interact, accelerating the decay of an excited state to a lower excited state or to the ground state. This interaction may take place in the excited state of the lumiphor and be collisional in nature. In this situation the process is referred to as dynamic quenching. The excitation energy is transferred to the quencher and is nonradiatively dissipated. Alternatively, the lumiphor and the quencher may associate in the ground state, forming a species that does not display the original luminescence characteristics. This process is known as static quenching.

In a phosphorescence measurement, if quenching is included in Equation (3), the rate of deactivation from the triplet state T_1 is (Equation 13)

$$\text{rate}_p = -(k_p + k_{st}^i + k_q[Q])[T_1] \quad (13)$$
where \([Q]\) is the quencher concentration and \(k_q\) is the bimolecular quenching rate. Thus, the phosphorescence quantum yield in presence of a quencher is (Equation 14)

\[
\Phi_p^q = \frac{k_p}{(k_p + k_{is} + k_q[Q])} \frac{k_{is}}{k_{is} + k_q[Q]}
\]  

(14)

Dividing Equation (11) by Equation (14), the ratio of quantum yields in the absence of quencher \((\Phi_p^0)\) and in the presence of quencher \((\Phi_p^q)\) yields Equation (15):

\[
\frac{\Phi_p^q}{\Phi_p^0} = \frac{k_p + k_{is} + k_q[Q]}{k_p + k_{is}} = 1 + \frac{k_q}{k_p + k_{is}}[Q]
\]  

(15)

Using Equation (4),

\[
\frac{\Phi_p^q}{\Phi_p^0} = 1 + k_q \tau_t[Q] = 1 + K_q[Q]
\]  

(16)

Equation (16) is known as the Stern–Volmer relationship, in which \(K_q\) is the Stern–Volmer quenching constant and \(\tau_t\) is the observed triplet lifetime in the absence of quencher. This equation states that plots of \(\Phi_p^q/\Phi_p^0\) versus \([Q]\) should be linear with a slope equal to \(K_q\). In the case of dynamic quenching, the slope of the plot, \(K_q\), is \(\tau_t k_q\). For static quenching \(K_q\) is the binding constant of the ground-state complex between the phosphor and the quencher.

Generally, the quencher concentration is always much larger than the concentration of excited molecules being quenched. Then, the product \(k_q[Q]\) may be considered a constant as \([Q]\) is not substantially modified during the quenching process. In this case, the product \(k_q[Q]\) may be defined as a “pseudo-first-order rate constant” and the triplet state lifetime in the presence of quencher \(\tau_p^q\) is (Equation 17)

\[
\tau_p^q = \frac{1}{(k_p + k_{is} + k_q[Q])}
\]  

(17)

The oxygen molecule in its stable ground state is paramagnetic, having two unpaired electrons in different orbitals. Such an electronic configuration, called a triplet, is unusual for ground-state molecules. Oxygen in this state is a potent quencher, especially of the triplet states, quenching almost all organic phosphors.

Oxygen quenching is diffusion limited and may be described by a modified Stern–Volmer relationship which holds for both fluorescence and phosphorescence and for both lifetimes and intensities (Equation 18):

\[
\frac{I_0}{I} = \tau^0 = 1 + k_q \tau^0[O_2]
\]  

(18)

in which \(I_0\), \(\tau^0\) and \(I\), \(\tau\) are the intensities and lifetimes in the absence of oxygen and at an oxygen concentration \([O_2]\), respectively. In the most simplistic terms, Equation (18) means that when \(O_2\) interacts with a lumiphor it decreases the luminescence intensity and shortens its lifetime.

### 3 INSTRUMENTATION

The equipment required for measuring phosphorescence intensities, lifetimes, excitation and emission spectra are commercially available. Those instruments may be used in low-temperature phosphorescence, MSRTP, and SSRTP, as well as in solution-sensitized RTP work, with no or minor instrumental modifications.\(^7,12,13\)

The major components of fluorescence and phosphorescence instrumentation include a source for exciting radiation, an excitation wavelength selector system, a sample cell, an emission wavelength selector system, and a detector (Figure 2).

Taking advantage of its long lifetime, phosphorescence can be measured in the absence of fluorescence by using a phosphoroscope, a device which allows excitation light to be gated in time.\(^14\) Therefore, if incident radiation is cut off, prompt fluorescence and direct scattering cease almost immediately. However, phosphorescence remains and can be detected free of interference from fluorescence for some time afterwards. Two types of shutter systems are commonly employed:

- The Aminco–Keirs phosphoroscope, in which the sample cell is surrounded by a rotating cylinder with two diametrically opposite apertures. The emitted phosphorescence is collected at right angles to the excitation radiation. The delay between excitation and emission is determined by the speed of rotation and the length of each observation which is determined by the size of the window.

- The Becquerel phosphoroscope, in which the sample cell is placed between two circular rotating discs with opposing 90° sectors cut out of each disk. The duration of each burst of radiation and the delay between them are determined by the speed of rotation. Unlike

![Figure 2 Layout of a typical phosphorescence spectrometer.](image-url)
PHOSPHORESCENCE MEASUREMENTS, APPLICATIONS OF

the Aminco–Keirs phosphoroscope, this shutter system requires $180^\circ$ geometry and is not so extensively used. Earlier phosphorimeters used these mechanical chopping systems with a continuous excitation source (e.g. xenon arc lamp, a high-pressure mercury lamp or a tungsten incandescent lamp).

Instrumentation for improved acquisition and analysis of phosphorescence lifetime decays have come to the fore with the increasing use of microprocessors and pulsed sources in luminescence works.

Figure 3 illustrates three cycles of sample excitation and observation for a pulsed-source-gated-detector phosphorimeter. With an initial pulse of source energy, with a duration $t_f$ (typically about 10 µs), the phosphorescence intensity reaches a maximum value and then decays exponentially. At a delay time $t_d$, after which the source flash has decayed, the photomultiplier detector is turned on, and the integrated phosphorescence signal is measured during the on time ($t_g$). The photomultiplier detector is then turned off and the sequence repeated. Pulsed source-time resolved phosphorimetry was first proposed by Fisher and Winefordner in 1972.\(^\text{15}\)

The advantages of pulsed-source-time-resolved phosphorimeters over conventional instruments with mechanical modulation are:

- A higher source peak intensity can be produced during the pulse without overheating the lamp as the thermal energy is dissipated during the dark periods between the pulses.
- The possibility of improving selectivity for a short-lived phosphor compared to a long-lived phosphor.
- The possibility of measuring phosphors with short lifetimes ($0.1$–$50$ ms).\(^\text{16}\)

The performances of mechanical systems are limited by the maximum speed of rotation available.

- Control over the timing parameters allows the analytical potential of phosphorimetry to be extended, such as the possibility of analyzing mixtures of phosphorescent compounds having different lifetimes.

4 OPERATING PRINCIPLES AND APPLICATIONS

4.1 Low-temperature Phosphorimetry

Low-temperature phosphorimetry from solutions was considered for years as the way of obtaining analytically useful phosphorescence signals. However, low-temperature phosphorescence has not become a popular analytical method because of the need for cryogenic cooling, the irreproducibility of the formation of the cooled matrix, and the problems related to sample introduction into the phosphorimetric system.\(^\text{17}\)

Up to the present time, the immersion method has been widely used for cooling the sample, which is lowered into a quartz Dewar flask filled with a coolant. Among the possible coolants (liquid nitrogen, oxygen, rare gases, air) only liquid nitrogen is safe, inexpensive and pure enough to be non-luminescent and transparent at all wavelengths between 200 nm and 800 nm.

Depending on the rate of sample cell cooling and the chemical nature and composition of the solvent system, the cooled matrix can be a clear glass, a cracked glass, or a snow. When the capillary tube makes contact with liquid nitrogen, the sample cools very quickly, and cracked glasses or snows result for most solvents. This problem can be avoided if the capillary tube is gradually cooled over the liquid nitrogen before contact is made.

Only a few solvents form clear glasses at low temperature, the most notable being ethanol, isopentane, and \(n\)-propanol. However, several solvents that are not useful alone do form good mixed solvents. So, ethanol has been combined with a variety of other solvents, the most popular of the mixed solvents being EPA, a 5:5:2 (by volume) mixture of ether, isopentane, and ethanol.

The above practical disadvantages can be minimized by using a device based on conduction cooling of a short capillary sample cell in a copper block cooled by liquid nitrogen. These devices allow improved sample turnover time to about one sample per minute, it is not necessary to handle Dewar flasks, and the amount of liquid nitrogen is reduced. Unfortunately, it is difficult to obtain good thermal contact between the sample cell and the copper block. Also, it is not easy to thermally insulate the cooling device, which results in difficult quantitative analysis due to fogging of the view area.
4.2 Solid-surface Room Temperature Phosphorimetry

Roth\(^{18}\) in 1967, first listed the RTP detection limits of 18 organic compounds adsorbed on filter paper. Since this report, the field of analytical SSRTP has expanded considerably.\(^ {19–23} \) Only certain materials are useful for inducing RTP from adsorbed phosphors, among which filter paper is the most widely used. Nearly all of the solid materials employed to develop RTP give phosphorescence background signals. Only sodium acetate has a low background emission. Thus one criterion for selection of a solid surface is to measure the relative RTP signal of the sample compared to the background RTP of the solid surface. Vo-Dinh\(^ {13}\) compared about 20 different kinds of commercial filter papers using pyrene as a model analyte. It was found that the difference in performance between papers was substantially less than an order of magnitude.

In RTP work, the solvent used to deposit the phosphor on the solid substrate can influence the final RTP signal. Acidic, alkaline and neutral solutions have been used in a number of applications. Also, ethanol–water mixtures have been extensively employed. In order to produce spots yielding rapid and reproducible results, a microsyringe or a micropipet is used to deliver the sample to the surface. Once the phosphor is spotted on the solid surface, it is necessary to dry the adsorbed sample prior to the RTP measurement step. In fact, moisture is one of the main factors that drastically diminish the RTP signal. There are different ways to dry the sample: blowing hot air onto the sample, placing the sample inside a desiccator, heating the sample inside an oven, or placing the sample under an infrared heating lamp. The use of an infrared heating lamp has been found to be very practical as the method is rapid (3–5 min compared with 1–5 h in a desiccator), convenient and, usually, nondestructive. The dry sample is kept dry during RTP measurement by passing a flow of air, nitrogen, or argon through the sample compartment. The main steps of an RTP assay are shown in Figure 4 for the method using filter paper.

There is no general model that explains the interactions required to develop RTP from compounds spotted on solid supports. It has been proposed that hydrogen bonding of polar or ionic organic compounds to the hydroxyl groups of the paper (or to the surface silanol groups of silica gel) is the main mechanism that provides the rigidity required to restrict collisional quenching of phosphor molecules in the triplet state. In this single working model, the moisture effect is explained by assuming that water molecules disrupt the hydrogen bonding, thus facilitating oxygen accessibility to the phosphor in the sample matrix.

So far, the analytical potential of SSRTP has been hampered by its discontinuous character, the necessary sample manipulation, support background, and water/oxygen quenching, which limit conventional practical work. Attempts have been made to develop an automatic instrument for SSRTP based on a continuous filter paper on which the samples were sprayed using a conventional atomic absorption nebulizer (Figure 5).

Promising uses for SSRTP include the development of fiber optical chemical sensors. Campiglia and Vo-Dinh\(^ {24}\) have reported the development of a universal RTP sensor adaptable to different analytical situations involving phosphorescent compounds. Filter paper

pretreated with thallium(I) acetate was used as a solid support to increase phosphorescence emission from several model polycyclic aromatic hydrocarbons (PAHs) and nitrogen heterocyclic compounds. Advantage was taken of coupling fiber optics into a pulsed nitrogen laser excitation source to measure RTP emission from compound imbibed on the filter paper. Detection limits at the nanogram per liter level were estimated for all the compounds studied. Reproducibility, highly dependent on drying conditions, ranged from 6.1% for chrysene to 11.9% for 7,8-benzoquinoline. Linear dynamic ranges extended over 2–3 orders of magnitude.

In spite of the generally accepted idea that water adversely affects SSRTP, it has been demonstrated that analytically useful SSRTP can be observed in a continuous aqueous flow provided that the solid support is adequately selected for a given phosphor. The solid support is conveniently packed into a flow cell and the analyte introduced into the flow system, either continuously or by means of an injection valve. The approach involves the integration of the basic reaction/retention/detection processes at the solid support in the flow cell. This detection principle in flow analysis is known as optosensing at active surfaces.

RTP optosensing is an important new development in phosphorimetry. Not only can conventional organic phosphors be determined, but also metal ions, anions, surfactants, antibiotics, gases, and vapors (e.g. oxygen, humidity). The favorable analytical performance of RTP optosensing systems for oxygen, allows its use as an optical transducer for enzymatic biosensing in oxygen-mediated reactions, both in solution (e.g. glucose determination) or in a gaseous environment (e.g. ethanol determination; Table 1). It is clear that the combination of flow analysis and SSRTP offer promising new analytical possibilities to phosphorimetry, particularly in the field of optical sensing.36

### 4.3 Room Temperature Phosphorescence in Ordered Media

#### 4.3.1 Organized Surfactant Assemblies: Micelle Stabilized Room Temperature Phosphorescence

Surface active agents (surfactants) are amphiphilic molecules in which a polar head group is attached to a long nonpolar chain. The nonpolar moiety is usually a hydrocarbon tail and the polar region, the head, can be either an ionic or a polar neutral group. These amphiphilic molecules associate dynamically in solution to form relatively well-defined assemblies termed micelles. Micelle formation starts at a characteristic surfactant concentration, the critical micelle concentration (CMC). In aqueous solution, individual surfactant molecules aggregate in such a way that the hydrophobic tails are packed together, forming a nonpolar core, while the hydrophilic heads face the aqueous solution, forming a boundary surface between the core and the isotropic aqueous solution.

An understanding of the organized assembly effect, together with the knowledge of the degree of interaction between the organized medium and the luminescence system being examined, are the keys in developing new analytical luminescence methodologies. In fact, the degree and type of binding between any lumiphor-organized system combination depend on the hydrophobic–coulombic net interactions. These are determined by the relative chemical nature of the luminescent probe and that of the organized medium considered. In this sense, localization of a lumiphore in a given micellar medium may be in any or all of several regions of the aggregate. An amphiphilic solute may align itself with the polar portion in the surface layer of the micelle with the tail directed inward, towards the core of the micelle. Ionic species with an opposite charge to the micellar aggregate may be bound to the micellar surface by electrostatic attraction. Nonpolar species may penetrate to a particular depth into the surface layer.

Normal micelles have been the organized media more commonly used to develop analytically useful RTP in fluid solutions. In a conventional experiment, the luminescent molecule is dissolved in a sodium lauryl sulfate (SLS) micellar solution and then diluted with thallium lauryl sulfate (TILS)/SLS solution to obtain a total detergent concentration of 0.10 mol L\(^{-1}\) and a 30:70 ratio of Ti/Na. The solution is finally deoxygenated by purging with nitrogen for 15–20 min and analyzed using time discrimination.

### 4.3.2 Principles and Applications of Micelle Stabilized Room Temperature Phosphorescence

MSRTP was first reported by Kalyanasundaram et al.\(^{(37)}\). Cline Love and Weinberger\(^{(38)}\) showed that three fundamental requirements are necessary to develop analytically useful MSRTP for most lumiphors: securing the presence of micellar aggregates (using a surfactant concentration above its CMC), the presence of a heavy atom or a heavy species, and securing oxygen removal.

RTP can be observed from many molecules in fluid solution by incorporating the phosphor into a micellar system. The protective effect of the micellar microenvironment greatly minimizes collisional deactivation of triplet species by restricting their diffusive motions. Only at surfactant concentrations well above the CMC is the protective effect on phosphorescence observed (micellar effect). An additional factor that favorably influences the RTP observed is the relative micelle/phosphor polarity and/or charge. So, no MSRTP is observed in anionic micellar media for negatively charged molecules. However, these negatively charged phosphors experience, in a cationic micellar medium, attractive electrostatic interactions acting concurrently with the hydrophobic ones to provide the necessary immobilization for the observed strong RTP signals.

However, micelles can be functionalized with a heavy atom; for example, the counterion of anionic micelles can be replaced by a heavy element such as silver or thallium. The local effective concentration of the heavy atom in the micelle is then larger than its actual molar concentration. The intrinsic proximity between the phosphor solubilized in the micelle and the heavy counterions results in a heavy atom effect, thus enhancing the rate of intersystem crossing. It is known that the presence of heavy atom perturbers results in shorter phosphorescence lifetimes and causes a considerable reduction of fluorescence emission. Adequate choice of surfactant assemblies and heavy atoms allows one to observe analytically useful MSRTP from a variety of compounds. For example, MSRTP has been observed from polynuclear aromatic and heterocyclic compounds solubilized in SLS anionic micelles and in the presence of thallium, silver, or lead as heavy atom perturbers.\(^{(38)}\)

Oxygen is a potent quencher of the excited triplet state. Micellar media provide a microenvironment that can protect a solubilized phosphor from interactions with oxygen allowing for MSRTP in some solutions that have not been deoxygenated. In order to enhance MSRTP, oxygen removal is usually carried out by using an inert gas (e.g. nitrogen). Diaz-Garcia and Sanz Medel\(^{(39)}\) studied in detail the use of sodium sulfite as a chemical oxygen scavenger for MSRTP (Equation 19).

\[
2\text{SO}_3^{2-} + \text{O}_2 \rightarrow 2\text{SO}_4^{2-} \quad (19)
\]

The method is simple and reliable. The analytical performance of MSRTP with sulfite deoxygenation was tested for determination of arenes,\(^{(40)}\) metals (Table 2), nucleic acids\(^{(45)}\) as well as for immunoassays.\(^{(46)}\) This simple technique can be extended to chemical deoxygenation of other organized media such as vesicles and CDs to develop RTP in solution,\(^{(47)}\) as well as in flowing systems.\(^{(48)}\) MSRTP provides limits of detection for many aromatic molecules in the nanomole per liter range and calibration graphs have a wide linear range. The overall precision is about 5%. It is worth mentioning the high sensitivity observed if one considers the high probability of nonradiative pathways that may occur in solution at room temperature.

Cline Love and Weinberger\(^{(38)}\) have demonstrated that MSRTP techniques can be applied for detection of phosphors in liquid chromatography in two different approaches:

- Using the micellar solution as a mobile phase.

different PAHs was described in detail using an SLS/TILS (70%/30%) micellar mobile phase and a propylcyano-bonded column as stationary phase. Detection limits were in the nanogram range for PAHs investigated in coal liquids and wastewater products. Working ranges covered more than three orders of magnitude.

- In a postcolumn addition mode, the micellar phase is merged with the mobile phase after chromatographic separation, as demonstrated for aromatic compounds.

Detergents have also been used in paper-substrate RTP, leading to signal enhancements in the twofold to ninefold range for PAHs adsorbed on filter paper impregnated with Tl/SLS. The main interactions proposed in this system do not involve the presence of micelles but the enhancement is due to improved heavy atom/phosphor proximity and to an increased migration of the species through the cellulose pores of the paper.

4.4 Cyclodextrin Room Temperature Phosphorescence

CDs are cyclic oligosaccharides composed of \(\alpha-(1 \rightarrow 4)\)-linked D-glucopyranose units forming thus a truncated cone-shaped structure with a central cavity. The best-known members of this class of natural products are \(\alpha-, \beta-,\) and \(\gamma-\)CDs, as they are commonly referred to, composed of six, seven, and eight glucose units, respectively. The hydrophilic hydroxyl groups of the glucose units occupy both rims of the cone, rendering the CDs soluble in water, whereas the cavity, lined by hydrogen atoms and the glycosidic oxygen bridges, is relatively hydrophobic compared to water. Thus, CDs provide a microheterogeneous environment in water. The unique structural features of the CD cavity explain some of the unusual characteristics of these compounds.

Because of these structural properties, CDs can form inclusion complexes with guest molecules that fit into the cavity, even if only partially. Complexation is based on a combination of several intermolecular interactions, including hydrophobic, electrostatic and dipole–dipole interactions, dispersive forces, steric fit, and hydrogen bonding.

As a consequence of inclusion-complex formation, the microenvironment around the guest molecule in the CD cavity is different from that in the bulk media. In fact, inclusion of a lumiphor in a CD cavity results in important changes in the photophysical and/or photochemical properties of the guest. Analytical luminescence benefits that result from complexation with CDs include:

- Protection of excited states from collisional quenching and other nonradiative pathways. The cavity of the CD is a finite space in that, once it has been occupied by a lumiphor, other molecules are excluded from occupying the space at the same time. This prevents collisional encounters. Also, constraints imposed on the mobility of the guest reduce the rate of the radiationless transition of excited singlet and/or triplet states.
- Solubility enhancement of poorly water-soluble lumiphors.
- Partial protection of phosphor guests against quenching by dissolved oxygen in solution.

Although cyclodextrin room temperature phosphorescence (CDRTP) has not been widely used as an analytical technique, CDs have significant potential as ordered media to develop new RTP methodologies in solution. As in MSRT, a heavy atom (external or intramolecular) or a heavy structure (e.g. 2-bromoethane) should be present to populate the triplet state. Sample deoxygenation, either using a chemical scavenger as sodium sulfite or bubbling an inert gas, results in increased phosphorescence intensity.

In a conventional experiment for CDRTP analysis of PAHs an aliquot of the analyte of interest is added to a flask and the solvent is removed by gently heating on a hotplate. An aliquot of 1,2-dibromomethane (heavy atom perturber) is then added, followed by dilution with 0.01 mol L\(^{-1}\) aqueous CD solution. After shaking vigorously by hand, a cloudiness in the solution can appear due to precipitation of excess 1,2-dibromomethane complexed by CD. This turbidity has no influence on the reproducibility and quality of RTP spectra. Finally, the sample is de-areated for about 15 min with nitrogen and placed in a standard fluorescence cell with a Teflon\(^{6}\) stopper for RTP measurement. Following this method, sample preparation time is about 20 min.

4.5 Sensitized Room Temperature Phosphorescence in Liquid Solutions

Direct solution room temperature intensities are generally too low to be analytically useful. Donkerbroek et al.\(^{49}\) applied the technique of SP in liquid solutions as a useful alternative to direct solution RTP.

In SP the analyte (a weakly or nonphosphorescent species) is excited by means of light absorption. Subsequently, the analyte transfers its triplet energy to an acceptor molecule, thus producing an acceptor triplet with a high phosphorescent yield (Figure 6).

Sensitized RTP is observed under the following conditions:

- When the triplet state energy of the acceptor is lower than that of the donor and when the energy gap
Sensitized RTP has been observed for a variety of organic species (drugs, polynuclear aromatics, etc.) and compounds that do not fluoresce in liquid solutions. However, only about 10–15% of the molecules that meet the energy requirements are found to undergo SP. The energy requirements are found to undergo SP. The energy-transfer reaction, $\tau_D^p$ is the triplet lifetime of the donor (D) in the absence of the acceptor A, and $[A]$ is the acceptor concentration. Therefore, appreciable sensitized RTP will occur if $K_t[A] > 1/\tau_D^p$. This condition can be met if solvent deoxygenation is carried out.

- If absorption of excitation radiation by the acceptor is negligible.
- If there is an appreciable population of the donor’s triplet state.

Sensitized RTP has been observed for a variety of organic species (drugs, polynuclear aromatics, etc.) and compounds that do not fluoresce in liquid solutions. However, only about 10–15% of the molecules that meet the energy requirements are found to undergo SP. The potential acceptors found useful in sensitized RTP are limited, with biacetyl and 1,4-dibromonaphthalene being the acceptors of choice in many applications.

Sensitized RTP has been successfully applied as a detection method for both chromatographic and continuous-flow systems, and the approach can be considered as complementary to fluorescence detection. Spectroscopically, a drawback of sensitized RTP is that all spectral information about the donor is lost as the emission spectrum is that of the acceptor. The advantages of using SP are:

- The emission wavelength is constant because, for all donors, the same emitting species is employed.
- Analytes are detected at a relatively long emission wavelength of the acceptor, which results in minimizing the effects of background fluorescence and stray light.
- In principle, the approach could be useful for those compounds that phosphoresce in cryogenic conditions, because the primary condition to be fulfilled is an efficient triplet formation.

A complimentary technique with less requirements is quenched RTP in liquid solutions, in which quenching of biacetyl phosphorescence by the analyte acceptors is used to determine the latter. For sensitized RTP a suitable wavelength is used for analyte excitation and biacetyl phosphorescence is detected. However, in quenched RTP a wavelength is selected where the molar absorptivity of biacetyl is relatively high and it is the only species excited. Thus, the analyte (acting as an acceptor) leads to a decrease of the biacetyl RTP.

Donkerbroek et al.\textsuperscript{50} derived Equation (21),

$$
\frac{1}{I_{dir}} = \frac{1}{I_{dir}^{0}} + \frac{k_q[Q]}{I_{abs}^B \rho_{inc}^B k_P^B}
$$

where $I_{dir}$ is the direct RTP intensity of biacetyl in the absence of quencher (analyte), $I_{dir}^{0}$ is the RTP of biacetyl in the presence of quencher, $k_q$ is the bimolecular rate constant of the quenching reaction, $[Q]$ is the quencher concentration, $I_{abs}^B$ is the rate of light absorption by biacetyl, $\rho_{inc}^B$ is the triplet formation efficiency of biacetyl, and $k_P^B$ is the rate constant of the phosphorescence process.

As indicated by this equation, a straight line with a slope proportional to $k_q$ and an intercept equal to the inverted intensity of the nonquenched signal is obtained by plotting $1/I_{dir}$ versus $[Q]$. Therefore, for a particular analyte the sensitivity of the quenched RTP is proportional to the $k_q$ value. Donkerbroek et al.\textsuperscript{50} estimated the limit of detection (LOD) for various compound classes by quenched RTP using Equation (22):

$$
\text{LOD}(M) = \frac{10}{k_q(M^{-1} s^{-1})}
$$

Therefore, determination of $k_q$ for a number of analytes is of importance to evaluate the analytical potential of the approach. Quenched RTP in solution
holds considerable potential for use in continuous-flow detector systems. It can also be applicable to many compounds that may have inherently poor detection properties by other techniques. For example, it could be used for nonultraviolet-absorbing species detection in ion chromatography (nitrite, sulfite, cis-platin, etc.).

5 TECHNIQUES OF LIFETIME MEASUREMENTS

The commonly used approaches to measure luminescence lifetimes are time-resolved and phase-resolved measurements.\(^7\)

5.1 Time-resolved Measurement

In this method a pulsed radiation source excites the sample and the decay profile is monitored. If the excitation pulse is of very short duration (10 \(\mu\)s) and assuming that only a single decaying component is present, the emission is a monoexponential decay (Equation 23)

\[
I_{t=0}(\tau) = I_0 e^{-t/\tau} \tag{23}
\]

where \(I_{t=0}(\tau)\) is the phosphorescence intensity of the compound at a delay time \(t\), and \(I_0\) is the phosphorescence intensity at time \(t = 0\). The luminescence lifetime \(\tau\) is the mean excited state lifetime.

For a binary system of components A and B, the theoretical expressions for pulsed-source phosphorimetry are (Equation 24)

\[
\begin{align*}
I_{t=A}^{(A)} &= I_0^{(A)} e^{-t/\tau_A} \\
I_{t=B}^{(B)} &= I_0^{(B)} e^{-t/\tau_B} \\
I_{t=A+B}^{(A+B)} &= I_{t=A}^{(A)} + I_{t=B}^{(B)}
\end{align*}
\]

where \(I_{t=A+B}^{(A+B)}\) is the total phosphorescence intensity of the mixture. For multicomponent systems similar expressions may be derived.

This technique has important advantages over simple intensity measurements as it involves comparing the luminescence intensity at various times, it is self-referencing, and it compensates for factors such as changes in the efficiency of the source, detector, or electronics.

The three methods generally used to determine phosphor concentrations by time-resolved phosphorimetry are the multiple analytical curve method, the exponential method, and the logarithmic decay time method.\(^{12}\)

Time-resolved phosphorescence for organic compounds is now well established and was first suggested by Winefordner in 1969.\(^{51}\) Application of chemometric techniques to the interpretation of RTP emission spectrum–decay data and to simultaneous determinations of organic\(^{52}\) and inorganic\(^{53}\) species has also been reported recently.

5.2 Phase-resolved Measurement

This method allows phase resolution of the phosphorescence signal from phosphors with different lifetimes. The sample is excited using a source (usually a continuous-wave laser) whose light intensity is modulated at a frequency \(f\).

Table 3 summarizes the equations derived by Aaron and Winefordner, describing the phase and frequency characteristics of luminescence.\(^{54}\)

Phase-resolved phosphorimetry is especially useful for strong phosphors or concentrated solutions of weak phosphors if fluorescence or stray light interferences are not present. Also, it is adequate for short time analysis (<1 ns) of molecular decays, as the relative error decreases slightly with the faster decay times of the sample under study.

6 CONCLUSIONS

In spite of the fact that analytical applications of phosphorescence have been somewhat scarce in the past, the examples quoted in this article indicate the variety of possibilities for developing new highly selective, sensitive, simple and rapid phosphorimetric methodologies. With the recent advances in RTP, the introduction of new instrumentation, and the breadth of potential applications, the use of analytical phosphorimetric approaches is likely to increase.

The majority of effort in the future should go into the process of translating research findings into practical applications and/or commercially viable systems. Areas such as miniaturization and development of portable phosphorimeters, and the design and construction of phosphorimetric sensors to monitor analytes in a continuous way, should also deserve special attention, particularly in clinical chemistry and pharmaceutical and environmental fields.

1 Introduction

The physical and chemical characteristics of surfaces along with the structure and dynamics of molecules near surfaces or interfaces have recently become critically important. Surface measurements have provided important information concerning the properties of the surfaces and surface/adsorbate interactions. The physical, chemical and biological sciences have benefited tremendously from these studies, with significant developments being made in the areas of diagnostic devices, optical devices, electronic devices and sensors.

The specific behavior of macromolecules at or near surfaces, interfaces, and membranes is currently of primary interest in the biological sciences. Important applications include: adsorption of blood proteins on biomaterials in thrombogenesis research; the binding to and triggering of living cells by hormones, neurotransmitters and antigens; cell adhesion to various surfaces; the mechanism of electron transport in mitochondrial and photosynthetic membranes; and also reaction rate enhancement with membrane receptors by nonspecific adsorption and surface diffusion of ligands. However, investigation of biomolecular behavior at surfaces and interfaces remains a difficult task. Most of the common analytical methods available for investigation of surfaces either lack the extent of surface selectivity required or demand relatively harsh sample handling that severely limits the biological relevance of any results obtained. This article specifically describes ultraviolet/visible (UV/VIS) absorption and photoluminescence techniques applicable to analysis of surfaces or thin films.

1 INTRODUCTION

The physical and chemical characteristics of surfaces along with the structure and dynamics of molecules near surfaces or interfaces have recently become critically important. Surface measurements have provided important information concerning the properties of the surfaces and surface/adsorbate interactions. The physical, chemical and biological sciences have benefited tremendously from these studies, with significant developments being made in the areas of diagnostic devices, optical devices, electronic devices and sensors.

The specific behavior of macromolecules at or near surfaces, interfaces, and membranes is currently of primary interest in the biological sciences. Important applications include: adsorption of blood proteins on biomaterials in thrombogenesis research; the binding to and triggering of living cells by hormones, neurotransmitters and antigens; cell adhesion to various surfaces; the mechanism of electron transport in mitochondrial and photosynthetic membranes; and also reaction rate enhancement with membrane receptors by nonspecific adsorption and surface diffusion of ligands. However, investigation of biomolecular behavior at surfaces and interfaces remains a difficult task. Most of the common analytical methods available for investigation of surfaces either lack the extent of surface selectivity required or demand relatively harsh sample handling that severely limits the biological relevance of any results obtained.

The two general areas of electron and optical spectroscopies are both powerful tools for examining surfaces and studying interfaces. Electron spectroscopy mainly includes techniques such as X-ray photoelectron spectroscopy (XPS), Auger spectroscopy and secondary-ion mass spectrometry (SIMS). The main optical spectroscopy techniques are attenuated total reflectance (ATR), total internal reflection fluorescence (TIRF), total internal reflection Raman (TIRR), surface-enhanced Raman spectroscopy (SERS) and ellipsometry. This article is mainly concerned with the application of ATR and TIRF spectroscopy in the ultraviolet (UV) and visible (VIS) wavelength range for surface studies of molecular species. The most comprehensive treatment of the
fundamental optics that support both ATR and TIRF can be found in *Internal Reflection Spectroscopy*.\(^{(1)}\)

## 2 THEORY OF ABSORPTION AND LUMINESCENCE

Absorption and luminescence are photophysical processes observed in both atomic and molecular systems. Since excitation of the chemical system by absorption is a prerequisite to any subsequent luminescence, we will begin with a discussion of optical absorbance. Also, the discussion will be limited to molecular systems.

### 2.1 Ultraviolet/Visible Absorption

The interaction of light with matter can be described by combining the classical and quantum theories of light with the quantum concepts of molecular structure. Light is a form of electromagnetic radiation and exhibits a well-known dual nature in that it behaves both as a classical wave and as a particle. The propagation of light is described as a wave phenomenon and is therefore characterized by a wavelength \(\lambda\) and a frequency \(v\) which are related as shown in Equation (1)

\[
\lambda = \frac{c}{v}
\]  

(1)

where \(c\) is the speed of light in a vacuum.

Three primary processes are possible whenever light impinges upon matter. The light can either be transmitted without loss, scattered or absorbed by the medium. The last case involves a transfer of energy to the medium composed of molecules characterized by their respective electronic energy configurations. When light is absorbed, the electronic configuration is altered and the molecule is promoted to a higher energy level. Each molecule possesses a series of discrete energy levels. To move from a lower energy level to a higher one, the molecule must absorb an integral quantum of light that is equal to the difference in the two molecular energy levels (Equation 2).

\[
\Delta E = E_2 - E_1
\]  

(2)

A quantum of light is called a “photon” and is described by Equation (3)

\[
E = hv = \frac{hc}{\lambda}
\]  

(3)

where \(h\) is Planck’s constant. Therefore, the electronic transitions associated with the absorption of light can be characterized by the wavelength of light absorbed. The energy necessary to produce electronic transitions in most molecules corresponds to the 200–800 nm wavelength region, or the UV (200–350 nm) and VIS (350–800 nm) ranges. Particular structural features that lead to absorption are called “chromophores”. A more thorough discussion of structural effects on absorption can be found in the literature.\(^{(2)}\)

### 2.2 Luminescence

Although there are numerous types of luminescence, for the purposes of this article we are primarily concerned with two: fluorescence and phosphorescence. Of these two, fluorescence is by far the most popular for analytical methodologies. The analytical sensitivity and selectivity of molecular fluorescence is confirmed by the number and diversity of analytical applications published each year.\(^{(5)}\) Molecular fluorescence has proven especially valuable for the analysis of biological samples in which many of the molecules of interest exhibit fluorescence. The nature of fluorescence permits the examination of intracellular mechanisms and the detection of biologically active compounds present at very low concentrations.

The processes of molecular excitation and relaxation are illustrated graphically in Figure 1. The electronic energy levels represented by \(S_0\), \(S_1\) and \(S_2\) are the ground, first excited and second excited singlet states, respectively. The excited triplet state is represented by \(T_1\). A number of more closely spaced vibrational energy levels are associated with each electronic energy level. As shown in Equation (4), the excitation of a molecule to an excited singlet can occur owing to the absorption of a sufficiently energetic photon \((hv\_a, \text{ where } h \text{ is Planck’s constant and } v\_a \text{ is the frequency of the absorbed photon})

\[
S_0 + hv\_a \rightarrow S_1
\]  

(4)

Excitation can originate from any of the ground state vibration levels. However, at room temperature most of the molecules populate the lowest vibrational level of the ground state. Therefore, the energy needed to promote a molecule to the \(S_1\) state corresponds to the energy differences between the first vibrational level of \(S_0\) and any of the various vibrational levels of \(S_1\). This is a rapid process occurring within \(10^{-15}\) s.

There are numerous mechanisms of relaxation available to excited-state molecules. They are often classified as either radiative or nonradiative depending on whether the excess energy is released as a photon or as some other form of energy. For most fluorescent molecules the various nonradiative processes generally combine to relax the excited state molecule down to the lowest vibrational level of \(S_1\). Once the excited molecule relaxes to \(S_1\), \(v\_0\), the molecule can reach the ground state, \(S_0\), by releasing a photon. This radiative transition between states of the same multiplicity is called fluorescence. Deexcitation to
any of the vibrational levels of $S_0$ is possible and usually occurs in $10^{-6}$–$10^{-8}$ s. This, of course, is not possible in molecules where a more competitive (faster) mechanism of relaxation is available. The direct excitation from the lowest vibrational level of $S_0$ to the lowest vibrational level of $S_1$ and the subsequent relaxation to the lowest vibrational level of $S_0$ is called the “0–0” transition. This transition is seldom observed except in the gaseous or crystalline state. In solution, the photon $h\nu_f$ (Equation 5) emitted as fluorescence is generally of longer wavelength (less energy) than the photon $h\nu_a$ which is absorbed (Equation 4).

$$S_1, v_0 \rightarrow S_0, v_x + h\nu_f \quad (5)$$

Following fluorescence, further relaxation to $S_0, v_0$ is possible by vibrational relaxation. The energy difference between the absorbed photon and the emitted photon is called the Stokes shift and is observed owing to the fact that fluorescence generally occurs from the lowest vibrational level of $S_1$ to some upper vibrational level of $S_0$. Furthermore, fluorophores can lose excitation energy owing to solvent effects in solution.

It is also possible for a molecule to undergo intersystem crossing from $S_1$ to $T_1$, provided that the respective vibrational levels of the two electronic states are energetically similar. Once this happens the molecule is free to relax to the lowest vibrational level of $T_1$. At this point, a radiative deactivation is once again competitive (Equation 6).

$$T_1, v_0 \rightarrow S_0, v_x + h\nu_p \quad (6)$$

This is called phosphorescence and differs from fluorescence emission in two distinct ways. First, $T_1$ is generally lower in energy than $S_1$ so that phosphorescence emission is longer in wavelength than fluorescence. Also, since the occurrence of a radiative transition between states of different multiplicity has a low probability, the lifetime of phosphorescence ($10^{-4}$–$10$ s) is significantly longer than that of fluorescence. For this reason phosphorescence is more susceptible to quenching than fluorescence and is seldom observed in solution at room temperature.

### 3 ANALYTICAL INFORMATION

The total energy of the molecule is the sum of electronic, vibrational and rotational energies such that for each electronic state several vibrational and rotational sublevels are possible. This results in relatively broad absorbance spectra and minimal qualitative information content useful for sample identification purposes. However, quantitative applications are well documented based on the relationship commonly called Beer’s Law (Equation 7).

$$A = -\log T = abc \quad (7)$$

In this equation, $A$ is absorbance, $T$ is transmittance, $a$ is the absorptivity constant, $b$ is optical pathlength, and $c$ is sample concentration. Linear behavior is generally observed at concentrations below 0.01 M. Assuming a good absorber, a typical commercially available absorbance spectrophotometer can provide detection limits in the low nanomolar range. A typical commercial double-beam absorbance spectrophotometer is shown in Figure 2.
**Figure 2** Double-beam absorbance spectrophotometer.

A detailed evaluation of the kinetics of fluorescence provides several analytically useful quantities that are necessary for the derivation of the quantitative aspects of the fluorescence measurement. Fluorescence is a first-order process with the rate of fluorescence depending on the concentration of excited molecules in S<sub>1</sub>, as shown in Equation (8).

\[
\frac{d(I_f)}{dt} = k_f[S_1]
\]  

(8)

The rate of production of [S<sub>1</sub>] is equal to the rate of light absorption, I<sub>a</sub>, as shown in Equation (9).

\[
\frac{d[S_1]}{dt} = I_a
\]  

(9)

If illumination is maintained over several fluorescence lifetimes, a steady-state relationship between the rate of absorption, I<sub>a</sub>, and the rate of fluorescence, k<sub>f</sub>[S<sub>1</sub>], is achieved (Equation 10).

\[
I_a = k_f[S_1]
\]  

(10)

However, Equation (10) is valid only in cases where there are no other processes competing with fluorescence for the deactivation of the excited state. A more realistic approach, shown in Equation (11), considers all of the possible relation processes.

\[
I_a = (k_f + k_{IC} + k_{ISC} + k_{O}[O])[S_1]
\]  

(11)

Each k represents the first-order rate constant for the respective processes described previously in Figure 1. If Equation (11) is rearranged and substituted for [S<sub>1</sub>] in Equation (8) it yields the relationship shown in Equation (12), in which the rate, or intensity, of fluorescence is equal to the rate of absorption multiplied by the quantum efficiency, \( \Phi_f \).

\[
I_f = \frac{d(I_f)}{dt} = I_a \Phi_f
\]  

(12)

The quantum efficiency, \( \Phi_f \), is the ratio of the rate constant for fluorescence without any competition and with competition (Equation 13).

\[
\Phi_f = \frac{k_f}{k_f + k_{IC} + k_{ISC} + k_{O}[O]}
\]  

(13)

In simpler terms, \( \Phi_f \) is given by Equation (14).

\[
\Phi_f = \frac{\text{Number of photons emitted}}{\text{Number of photons absorbed}}
\]  

(14)

One divided by the denominator in Equation (13) is called the natural fluorescence lifetime, \( t \), and is the time required for the fluorescence intensity to decay to 1/e times its initial value.

The preceding discussion (Equation 12) demonstrated that the intensity of fluorescence \( I_f \) is equal to the rate of absorption \( I_a \) multiplied by the fluorescence quantum efficiency \( \Phi_f \). According to the Beer–Lambert law the amount of light absorbed by matter can be described by the differential Equation (15)

\[-\frac{df}{dx} = kIc\]

(15)

where \( I \) is the intensity of light, \( x \) is the distance through the medium which it passes, \( k \) is a first-order rate constant and \( c \) is the concentration of the absorbing species. When this is integrated over a distance, \( b \), the popular form of absorbance Equation (16) is produced.

\[A = \log(I_f/I_0) = 2.3abc\]

(16)

In this form, \( A \) is the absorbance, \( I_f \) is the transmitted light, \( I_0 \) is the incident light, and \( a \) is the absorptivity. The amount of the incident light that is absorbed by the fluorescent sample is given by Equation (17).

\[I_f - I_0 = I_0(1 - 10^{-2.3abc})\]

(17)

This can be substituted for \( I_a \) in Equation (12) and expanded as a Taylor series to remove the exponential term. For dilute solutions in which the total absorbance is low (<0.01 AU), the Taylor expansion can be truncated. This produces a linear relationship between \( I_f \) and the fluorophore concentration \( c \), as shown in Equation (18).

\[I_f = 2.3I_0\Phi_f abc\]

(18)

At higher absorbances, the equation is no longer linear owing to a significant attenuation of the incident light as it passes through the sample.

The sensitivity of a given technique is defined as the amount of signal produced per unit concentration (or weight) of the sample. This is determined by the slope of a standard calibration curve. Equation (18) indicates the slope of a fluorescence calibration curve to be equal to 2.3\( I_0\Phi_f ab \). Therefore, the sensitivity of the fluorescence measurement can be regulated by adjusting the intensity...
of the exciting light ($I_0$). This provides experimental versatility with fluorescence that is unavailable from absorption spectroscopy.

In the literature, sensitivity is often confused with detection limit. The detection limit is the minimum detectable quantity of an analyte. This value is more often determined by background interferences and detector noise levels than by the sensitivity. The low detection limits obtainable by fluorescence are well documented in the literature and are often 1000 times below those of UV/VIS absorption. In fact, single molecule detection by fluorescence has been well documented in the literature and is now becoming somewhat routine.

Fluorescence measurements are much more selective than most other analytical techniques. Since not all molecules fluoresce, the mere detection of fluorescence is selective. Also, since fluorescence generally originates from $S_1$, $\nu_0$, the fluorescence spectrum of a pure one-component sample is independent of the excitation spectrum. No matter what excitation wavelength is selected, the shape of the emission spectrum will be the same. This fact provides the theoretical basis for the analysis of multicomponent samples. An optical diagram of a typical fluorescence spectrophotometer is shown in Figure 3.

4 FABRICATION OF THIN FILMS

4.1 Physical Deposition

The two main methods for producing thin, inorganic, surface coating films are vacuum sputtering and chemical vapor deposition (CVD). These techniques typically give reproducible high-quality films whose properties can be controlled within a certain range by variation of sputtering or chemical deposition parameters. Different modifications of vacuum sputtering and CVD are widely used in the optical industry to manufacture metal, metal oxide and metal halide coatings.

Thin polymer layers on solid supports are prepared by casting from polymer solution. Spinning of the substrate more often provides uniform thickness of the film. To manufacture large volumes of surface-supported films, the method of casting onto a linearly moving substrate is applied. To provide better adhesion of the polymer film, the substrate surface can be chemically modified. For example, simple treatment of glass with siloxanes dramatically enhances the adhesion of many polymers to originally hydrophilic glass surfaces.

Another powerful technique for thin organic layer preparation involves the Langmuir–Blodgett method of monolayer formation at the air–water interface. In principle, this technique can be applied for fabrication of thin films of a vast variety of organic compounds. However, the Langmuir–Blodgett method works better for amphiphilic molecules which comprise both hydrophilic and hydrophobic parts. Surface density and orientation of amphiphilic molecules can be controlled using a Langmuir–Blodgett balance. Since 1990, a renaissance of research on molecular organization stimulated the development of sophisticated Langmuir–Blodgett balances with capabilities of automated well-controlled deposition of organic monolayers and multilayers. A very complex multilayer molecular architecture of a sandwich type, which consists of a sequence of different compound monolayers, can be built at a solid surface.

4.2 Chemically Modified Surfaces

Surface chemistry is one of the parameters that determines the main features of the interfacial behavior of an adsorbate. The surface of a substrate can be modified by casting a thin polymer film, by vacuum deposition or CVD of an inorganic film, or by irreversible adsorption of macromolecules such as synthetic and natural biopolymers. Chemical modification of a thin monomolecular layer of a substrate is one of the most efficient ways to obtain a well-characterized solid surface with the desired properties. Numerous methods for chemical modification of inorganic and organic surfaces have been reported. This section describes selected methods of chemical modification of inorganic substrates such as glass, quartz and metal oxides, and focuses on procedures designed for covalent attachment of biological molecules.

Silane chemistry is one of the most widely used technologies to covalently attach a reactive group to the surface of an inorganic substrate. Different derivatives of trialkoxysilane compounds tipped with a variety of reactive groups are available commercially and can be used as coupling agents for covalent binding of proteins, DNA and other biomolecules of interest. These reagents bind to oxide surfaces via silane bonds. The opposite, free end of the silane reagent, that can carry such groups
as −NH₂, −COOH, or other reactive groups, is used to functionalize the surface by subsequent coupling of biomolecules. Triethoxysilanes are the most widely used compounds that react with the free hydroxyl groups of metal oxides by Sn2 exchange of the silane ethoxy groups for the silanol oxygen, with loss of ethanol. The reaction is catalyzed in the presence of a base. If the triethoxysilane derivative contains a primary amine group, the reaction is self-catalyzed, making external catalysis by a base unnecessary. In the catalyzed reaction, the base substitutes one ethoxy group of triethoxysilane, and a pentacoordinate silane intermediate is formed when a surface hydroxyl group replaces the base.

The purpose of the chemical modification is to obtain a monolayer or a submonolayer coating with active reactive sites at the tip of the attached molecule. However, in the case of the silanization, a multilayer silane film tends to occur instead of a mono- or submonolayer coating. This disadvantage can be avoided by proper selection of the silanization procedure. The silanization reaction dramatically depends on reaction conditions, and post-reaction “curing”. Since the formation of siloxane bonds is possible between two surface-bound molecules (horizontal polymerization) and between triethoxysilane molecules in solution and at the surface, multilayer siloxane films tend to be obtained at excessive concentrations and time of reaction. A monolayer siloxane coating is formed during several minutes of exposure of a glass or silica surface to a trialkoxysilane solution in a dry solvent such as toluene or xylene at room temperature. Thus, a monolayer coating can be obtained by reducing the reaction time and/or concentration of the reagent.

Silanization procedures utilizing aqueous solutions of trialkoxysilanes have also been reported. However, these coatings typically exhibit poor stability, and functionalized coatings can be desorbed by washing. One reason for this behavior is related to the electrostatic interactions between oxide surfaces and triethoxysilane compounds containing amines. Since glass and silica surfaces are negatively charged over a wide pH range, aminated coatings can be desorbed by washing. One reason for this behavior is related to the electrostatic interactions between oxide surfaces and triethoxysilane compounds containing amines. Since glass and silica surfaces are negatively charged over a wide pH range, aminated triethoxysilane derivatives tend to be adsorbed owing to electrostatic interactions between positively charged amine groups and a negatively charged surface. Subsequent curing of the surface with an adsorbed amine derivative of triethoxysilane at 100–120°C is required to stimulate transformation of the adsorbed compound to covalent binding via a silane bond. The functional activity of immobilized biomolecules depends on the chemistry and the length of spacer units between the triethoxysilane groups and the reactive group involved in the coupling of biomolecules. Relatively long spacer groups of 4–8 carbon atoms inserted between the reactive group (−NH₂, −COOH) and the surface-attaching triethoxysilane group allow better access of dissolved counterparts to the surface-attached functional group. In the case of short nonaliphatic spacers, surface-immobilized biomolecules frequently demonstrate reduction of their functional activity, which deteriorates significantly with storage time.

5 EXPERIMENTAL

5.1 Attenuated Total Reflectance

The total internal reflection (TIR) phenomenon can be explained with the aid of Figures 4 and 5. ATR is a term used with absorbance spectroscopy based on a common optical phenomenon called TIR. Application of TIR for ATR measurements has been most popular for vibrational absorbance with Fourier transform infrared (FTIR) spectroscopy. However, the fundamental principles are the same for ATR with the electronic absorbance applications of interest in this article. The principles of TIR were initially described by Newton in the early 18th century and are well documented in the more recent literature. (1, 7, 8) In brief, when a beam of light propagating within a medium of refractive index (n₁) encounters an interface with a medium of lower refractive index (n₂), it can undergo TIR for incidence angles (θ₁) greater than the critical angle (θc). Although the incident light totally reflects at the interface, a portion of the electromagnetic radiation penetrates the interface into the less dense medium. The intensity of this interfacial field, typically called the “evanescent wave”, decays exponentially with distance from the interface (Equation 19).

\[ \theta_c = \sin^{-1} \left( \frac{n_2}{n_1} \right) \]  \hspace{1cm} \text{(19)}

The penetration depth (d_p) of the evanescent wave in the less dense medium is a function of incidence angle, refractive index ratio and incident light wavelength, \( \lambda_1 \) (Equation 20). The penetration depth (pathlength) of the evanescent wave can be conveniently altered by changing incidence angles. The extremely short pathlength of the evanescent wave (in the order of the wavelength of light) excites a very small sample volume and thereby minimizes background absorption effects.

\[ d_p = \frac{\lambda_1}{2 \pi n_1 \sqrt{\sin^2 \Theta_1 - (n_2/n_1)^2}} \]  \hspace{1cm} \text{(20)}

Although light is efficiently propagated through the optical waveguide, the small proportion of energy present in the evanescent wave can be absorbed by surface components according to Beer’s law. The total light loss in the waveguide is the sum of losses due to scattering from the bulk sample and surface, respectively, and from surface absorbance. With appropriate experimental

5.1.1 Instrumentation

It is difficult to describe any general instrumentation scheme for waveguide detection because it can take many different forms depending on the particular application (Figure 6). It has been properly noted that “the true genius behind waveguide detectors lies in the reagent chemistry and geometry”. However, in general, the typical ATR waveguide device must provide for multiple reflections owing to the relatively poor sensitivity of absorbance measurements with extremely short pathlengths. The exact number of reflections can vary from <10 cm−1 with planar slab waveguides to several thousand per centimeter with integrated optical waveguides (IOW). However, it should be noted that, to date, IOWs have not become popularly applied owing to fabrication problems, high scattering losses and fluorescence background problems.

Associated instrumentation must provide for efficient optical coupling of light into the waveguide which is typically accomplished by either a prism or a grating coupler. Depending on the design of the waveguide, either broadband or monochromatic light can be used. Efficient detection in ATR also requires effective output coupling of the propagated beam into the appropriate detection device. Use of most of the common optical detectors (e.g. photodiodes, photomultiplier tubes, charge-coupled devices (CCDs)) has been reported in the literature in connection with ATR waveguide devices.

5.1.2 Applications

Initial applications of ATR for electronic spectroscopy of surfaces were primarily interested in increasing detection care, the attenuation of the evanescent wave by absorbance can be accurately calibrated for a quantitative measure of components contained within the penetration depth of the evanescent field.
sensitivity for surface adsorbates as compared with bulk transmission measurements. This was accomplished by use of multiple internal reflection waveguides which effectively increase the optical pathlength for the absorbance measurement while containing the optical beam parallel to the analytical surface. For example, Stephens and Bohn\textsuperscript{19} observed better than a 1000-fold enhancement in the absorbance detection of a chemisorbed p-nitrobenzoic acid monolayer on a 150\,\mu m glass waveguide compared with a traditional transmission experiment. They were also able to collect the absorbance spectrum of a 130\,\textnormal{nm} thick physisorbed film of phthalocyanine. Numerous other literature reports have cited similar sensitivity enhancements.

Closely paralleling those initial applications of ATR there appeared a large number of ATR-based sensor devices for various environmental and biological applications. For example, Yang and Saavedra\textsuperscript{12} reported development of a sol–gel-derived planar IOW for Pb(II) and pH. The sol–gel layer served as a porous yet stable support for the indicator phase. The thin (<200\,nm) sol–gel layer provided rapid response times. Several other similar sensors using various waveguide geometries have been reviewed by Dessy\textsuperscript{10}.

Several reports of the combination of waveguide optics with electrochemical techniques have also appeared in the literature.\textsuperscript{13–18} Dunphy et al.\textsuperscript{13} demonstrated a 10\textsuperscript{4} signal enhancement during the reduction of a submonolayer of surface-adsorbed methylene blue with a single-mode IOW coated with indium tin oxide as compared with a traditional transmission experiment. They estimated detectabilities of less than 1\% of a monolayer for most cases. It has been noted that a fundamental problem that has limited popular use of IOW/ATR devices concerns the difficulty in detecting the broadband spectrum, since both the mode propagation angle and the coupling angle are functions of wavelength. Therefore, the IOW is typically only efficient over a narrow wavelength band. Mendes et al.\textsuperscript{19} described a creative IOW design which combines a broadband Xe lamp with a prism input coupler and a series of two integrated gratings to compensate for wavelength dispersion in the IOW. A third output grating is then used to couple the dispersed ATR spectrum onto a CCD detector to provide simultaneous detection of the entire absorbance spectrum.

Some more recent reports\textsuperscript{20,21} have described the use of IOW/ATR for measurement of absorption linear dichroism. The combination of absorption linear dichroism with emission anisotropy measurements allows molecular orientation of surface species to be determined. This is a difficult question to resolve but highly relevant to many areas of biotechnology. Edminston et al.\textsuperscript{20} looked at the molecular orientation of cytochrome c on a variety of surface types, and Wood et al.\textsuperscript{21} studied the orientation of site-directed immobilization of cytochrome c on thiol-based self-assembled monolayers.

5.2 Total Internal Reflection Fluorescence

Hirschfeld\textsuperscript{22} first introduced TIRF in 1965, to examine solid/liquid interfaces. Since then many researchers have applied TIRF to examine various molecules at solid/solid, solid/liquid and liquid/liquid interfaces. TIRF is a surface-selective technique which is capable of detecting fluorescent probe molecules within a few hundred nanometers of the interface. The fluorescent probe molecules assist in investigating the interfacial chemical structure and environment. The probe molecules provide information about their surroundings by their spectral response, including spectral wavelength shifts, excited state lifetime and emission polarization.

TIRF spectroscopy has proven to be a very powerful and versatile technique for the study of surface and/or interfacial behavior of biological molecules and their aggregates.\textsuperscript{23,24} TIRF has been successfully applied to numerous studies associated with solute adsorption, orientation and rotational mobility associated with conformational changes. Surface selectivity is achieved in TIRF by detecting only the evanescent-wave-excited fluorescence signals which originate within approximately the first 100\,nm from the waveguide surface. This exceptionally short optical pathlength allows investigation of surface behavior even in the presence of highly concentrated solutions. In short, TIRF provides in situ, real-time, nondestructive, and highly sensitive detection suitable for studies on expensive biological materials available only in microliter quantities. Reliable detection of a few macromolecules per square micrometer has been documented with the utilization of commercial fluorescence spectrophotometers,\textsuperscript{25} while custom-designed systems allowed single-molecule detection.\textsuperscript{26}

The principles explained in section 5.1 for ATR apply equally to TIRF in respect to generation and behavior of the evanescent wave at the optically active surface. It is also important to understand the polarization properties of the evanescent wave, particularly for studies involving molecular orientation at the surface. The polarization properties of the transmitted field (evanescent wave) depend on the polarization properties of the incident light.\textsuperscript{27} For instance, if the incident electric field is s-polarized its electric field vector is perpendicular to the plane of incidence and the transmitted field has the same polarization as the incident field. However, if the incident electric field is p-polarized its electric field vector lies in the plane of incidence and the transmitted field is elliptically polarized. As a result, the s-polarization case is amenable to fluorescence anisotropy measurements.
of the interfacial region, whereas the p-polarization is considerably more complex. Additional properties of the evanescent wave and the underlying principles of TIRF are available in the literature.\(^1\)\(^2\)\(^7\)\(^8\)\(^9\) The evanescent wave is primarily responsible for the electronic excitation of the fluorophore present in the lower refractive index medium. The intensity of the fluorescence excited (Equation 21) in the evanescent volume is the integrated product of the intensity of the evanescent wave and the fluorophore concentration (\(C_z\)).\(^28\)

\[ I_{ex} = k_{ex} \phi I_i \int_0^\infty C_z e^{-z/d_p} dz \quad \text{(21)} \]

An important aspect of TIRF involves the reverse coupling of the emitted fluorescence back across the interface into the optical waveguide. The observed fluorescence depends on the observation angle (\(\theta_o\)). By the principle of reciprocity, the effect of the observation angle on this reverse coupling is similar to the effect of the incidence angle on the evanescent wave penetration depth. Therefore, at \(\theta_o\) greater than \(\theta_{co}\) the fluorescence intensity contained in the evanescent observation volume can be described by Equation (22).

\[ I_{em} = k_{em} \int_0^\infty e^{-z/d_p} dz \quad \text{(22)} \]

\(\theta_{co}\) differs from \(\theta_c\) (Equation 19) owing to the dependence of the refractive index on the fluorescence wavelength, \(\lambda_f\). In Equation (22), \(k_{em}\) is a proportionality constant and \(d_p\) is calculated using Equation (20) with \(\lambda_i\) and \(\theta_i\) replaced by \(\lambda_f\) and \(\theta_o\), respectively. Subsequently, the TIRF intensity reaching the detector (for fixed \(\theta_i > \theta_{ci}\) and fixed \(\theta_o > \theta_{co}\)) is the product of the two integrals in Equations (21) and (22) and can be represented by Equation (23), which is also referred to as a Laplace transform of the concentration–depth profile.

\[ I_t = k_{ex}k_{em}\phi I_i \int_0^\infty C_z e^{-z/(d_{pi}+d_{po})} dz \quad \text{(23)} \]

The TIRF signal can also be measured at a fixed observation angle for varying incidence angles which range from normal to grazing. Reciprocally, TIRF measurements can be made at a fixed incidence angle for varying observation angles which range from normal to grazing. (Both the incidence and observation angles are defined with respect to a normal to the interface.) This variable-angle technique is called variable-angle total internal reflection fluorescence (VATIRF). Generally, VATIRF data are represented as the variable-angle fluorescence intensity data curve. The data curve is a convolution of the fluorophore concentration–depth profile and the decaying evanescent wave. The complete concentration profile can be potentially extracted from the data by performing an inverse Laplace transform of Equation (23).

### 5.2.1 Instrumentation

Since the introduction of TIRF in the 1960s, waveguides and the associated instrumentation have generally been home-built and designed for specific applications. In 1995, the first general-purpose commercial TIRF cell was introduced. The design of the TIRF flow cell made the normally difficult TIRF experiment become routine. Figure 7 illustrates the basic optical design. The TIRF flow cell was prealigned for a specific commercial fluorometer and supplied with an easily assembled flow system to study kinetics of various surface interactions. This design provides high reproducibility of TIRF measurements by ensuring the exact positioning of optical elements against the excitation beam and emission axis. The TIRF cell differed from similar noncommercial TIRF cells.

---

Figure 7 Commercial version of TIRF cell.
in the simple and fast assembly of the sandwich cell. The transparent gasket which forms the flow chamber (approx. 20 µl) and the transparent back plate facilitate easy visualization of the surface and allow acquisition of microscopic pictures by a long-focus objective.

The cell was equipped with a UV-quartz dovetail prism and optically coupled cover slide, as shown in Figure 7. The cover slide provides an easily interchangeable working surface and minimizes wear on the TIRF prism. Cover slides with hydrophilic, hydrophobic and electroconductive thin films, or specific soluble protein docking films could be obtained depending on the application. The TIRF cell could be used with most of the popular, commercially available research-grade spectrofluorometers.

5.2.2 Applications

Although an extensive review of these areas is beyond the scope of this article, the following sections will attempt to highlight some particular applications in the areas of protein adsorption, polymer adsorption, biosensors and chromatographic surfaces by way of example.

5.2.2.1 Protein Adsorption

Using TIRF, protein adsorption at interfaces has been examined by intrinsic as well as extrinsic probes. External and internal standards have been used to quantitate the TIRF signal. Harrick and Leob (30) examined the adsorption of dansyl-labeled bovine serum albumin (BSA) onto sapphire and quartz surfaces. Adsorbed films were produced by immersing the internal reflection element (quartz or sapphire) into the solution of labeled protein. Multiple internal reflection elements with different geometries, a hemicylindrical prism and plates with 45° and 60° bevel angles with and without cavities, were used in the study. Van Wagener et al. (31) used the intrinsic fluorescence of proteins to monitor the adsorption of unlabeled proteins on quartz surfaces. This intrinsic method avoids the need to label the protein thus eliminating the possibility of altering the physicochemical properties of the protein. Rockhold et al. (32) developed a quantitative method to determine the amount of protein adsorbed on hydrophilic glass and quartz surfaces. The protein adsorption studies were performed by measuring the intrinsic protein fluorescence as well as extrinsic fluorescence from fluorescein-labeled protein.

Hlady et al. (33–36) studied protein adsorption on non-gradient and gradient surfaces. They examined the adsorption of BSA and human immunoglobulin at non-gradient and gradient silica/electrolyte interfaces. (33, 34) In a separate study they compared the adsorption of human high-density lipoproteins and low-density lipoproteins on hydrophilic and hydrophobic surfaces, respectively. The initial stage lipoprotein adsorption was of most interest. The adsorption of the two lipoproteins onto the two surfaces was found to be different. The lipoprotein adsorption on the hydrophilic surface was described quantitatively using a transport-limited adsorption model and assuming that the lipoprotein fluorescence quantum yield decreased upon adsorption.

TIRF spectroscopy was employed by Golander et al. (37) to quantify the adsorption of fluorescein-labeled lysozyme on bare mica and mica hydrophobized with a monolayer of 50% eicosyl amine (C20H41NH2) and 50% eicosyl alcohol (C20H41OH). The steady-state binding of a fluorogenic lysozyme substrate to an adsorbed lysozyme layer, and subsequent steady-state enzymatic cleavage of the substrate were also quantitatively studied using a TIRF cell. The relative binding and cleavage rates were found to be larger on the hydrophobic mica than on the bare mica. Based on the lysozyme structure and on measurements of enzyme activity, possible models were proposed for the orientations of lysozyme on bare and hydrophobic mica.

Lok et al. (38) examined the adsorption of proteins (BSA) from flowing solutions on polymer (cross-linked polymethylsiloxane) films. The results of the study showed that at high solution concentrations, the evanescent-wave-excited bulk solution fluorescence and fluorescence excited by scattered light contributed a significant fraction of the total fluorescence signal. The contribution of surface-adsorbed protein to the total fluorescence was determined by exchanging the labeled protein solution in the flow cell with an unlabeled solution. The observed initial fast decrease in fluorescence intensity on exchange with unlabeled solution was attributed entirely to the displacement of bulk-solution-labeled protein, and not to the removal of loosely adsorbed protein.

TIRF spectroscopy cannot independently provide information about the exchange kinetics of adsorbed protein molecules in chemical equilibrium with the bulk protein solution. To access the kinetics of exchange, a combination of TIRF with fluorescence recovery after photobleaching (FPR) or fluorescence correlation spectroscopy (FCS) was introduced by Thompson et al. (39). A theoretical basis was developed for measuring equilibrium adsorption/desorption kinetics and surface diffusion of fluorescent-labeled solute molecules at solid surfaces. In the TIRF/FPR technique, adsorbed molecules are irreversibly photobleached by a flash from a totally internally reflected laser beam. Subsequent fluorescence recovery is monitored by an evanescent field, as bleached molecules exchange with unbleached molecules from solution and the surrounding nonilluminated regions of the surface. In the TIRF/FCS technique, the evanescent intensity is maintained at a constant and fairly dim level all through the experiment. The spontaneous fluorescence fluctuations due to individual molecules entering and leaving a
well-defined portion of the evanescent field are autocorrelated. Under appropriate experimental conditions, the rate constants and diffusion coefficient can be obtained from TIRF/FPR and TIRF/FCS curves.

Burghardt and Axelrod\cite{40} applied the TIRF/FPR technique to study the dynamics of BSA adsorbed at a quartz glass/aqueous buffer interface. The technique allowed the measurements of desorption rates of rhodamine-labeled BSA and the detection of surface diffusion on a system in equilibrium without the need for any intrinsic spectroscopic change between the bound and unbound states. The data obtained revealed the presence of both irreversibly bound states and a multiplicity of reversibly bound states. The relative amount of reversible to irreversible adsorption was found to increase with increasing bulk protein concentration.

Burghardt and Axelrod\cite{41} studied the conformational and dynamical properties of adsorbed proteins by combining TIRF with conventional fluorescence spectroscopic examination of singlet–singlet energy transfer and fluorescence polarization. They constructed a TIRF apparatus which easily fitted inside the sample chamber of a commercial spectrofluorometer. BSA was multiply labeled with two donor–acceptor pairs of 4-chloro-7-nitro-2,1,3-benzoxadiazole–rhodamine and dansyl–eosin. The labeled BSA molecules were adsorbed at a quartz glass/aqueous buffer interface. The adsorbed protein was in equilibrium with the bulk solution. The spectral data exhibited significantly less effective singlet–singlet transfer from the donor to the acceptor in surface-adsorbed BSA relative to bulk-solution-dissolved BSA. With certain assumptions, this energy transfer change was interpreted as a conformational change of BSA upon adsorption.

Morrison and Weber\cite{42} employed TIRF polarization measurements to selectively examine fluorescent molecules adsorbed to the interface region between two immiscible liquids. A fluorescent compound bis-ANS (4,4’-bis(2-(5-phenylene-oxazolyl)benzene) was examined at a decalin/water interface. The adsorbed fluorophore displayed an apparently hindered rotation in the plane of the interface with rotational diffusion coefficients 3- to 12-fold lower than that expected for bis-ANS in solution. As a better approximation of a biological membrane, bis-ANS binding to the decalin/water interface was examined in the presence of a nonfluorescent surfactant, cetyltrimethylammonium bromide (CTAB). The addition of CTAB increased the affinity of bis-ANS for the interface. Also the addition of BSA was found to cause desorption of bis-ANS from the interface owing to competitive binding.

5.2.2.2 Polymer Adsorption

Masuhara et al.\cite{43} examined the interfacial characteristics of a polymer film on a sapphire substrate by time-resolved TIRF spectroscopy. In the study polystyrene films were doped with fluorescent p-bis(2-(5-phenylene-oxazolyl)benzene). Fluorescent decay curves were investigated as a function of incident angle. Monitoring the fluorescence helped to elucidate the photophysical processes and molecular motions in the nanosecond to picosecond time domains. As a further improvement of the technique, Itaya et al. performed the TIRF measurement under a microscope.\cite{44} This enabled them to obtain time- and space-resolved data on fluorescence characteristics.

Itaya et al.\cite{45} studied poly(methyl methacrylate) (PMMA) films doped with pyrene by TIRF. They examined the distribution of the dopant molecules in the polymer film and the microenvironment around the dopant molecules. The results were compared with fluorescence data obtained under normal excitation conditions. In these studies sapphire was used as an internal reflection element. Polymer films were both cast and film-coated onto the sapphire substrate. The concentration of the dopant molecule (pyrene) was varied in the experiments. The results indicated that micropolarity around pyrene molecules located at or near the sapphire/polymer film interface was higher than the bulk. Based on the pyrene monomer and excimer fluorescence data they concluded that the aggregate state of pyrene was significantly different at the interface and the bulk.

5.2.2.3 Biosensors

The development of convenient surface chemistries suitable for the attachment of biospecific molecules to waveguide surfaces has provided tremendous opportunities for the design of very sensitive and selective biosensor devices. The development and optimization of such devices is highly dependent on a thorough understanding of the molecular dynamics at the surface or interface. Both steady-state and lifetime-based TIRF techniques have been very useful for investigation of surface and interfacial behavior. An excellent review of lifetime-based TIRF applications for biosensors appeared in 1997.

Most of the biosensor development activity so far has centered on immunoassay reaction chemistries due to their inherent biospecificity and commercial availability. A large number and variety of TIRF biosensors has been reported. A thorough review appeared in 1991. Plowman et al.\cite{46} were the first to demonstrate femtomolar sensitivity for a model immunoassay system. This system consisted of a dual channel, 1-µm thick, siliconoxynitride IOW deposited on a 10-cm quartz wafer. A He–Ne laser was used for excitation and the emitted fluorescence was dispersed with a single grating spectrograph onto a CCD camera for simultaneous detection of both channels. This arrangement conveniently provided comparable sample
and reference spectra. More channels could be added for multianalyte applications.

One problem associated with TIRF biosensors is that a sensor with adequate sensitivity generally requires a biospecific interaction with high binding affinity. The affinity constants for most antibody–antigen interactions are determined largely by the dissociation constants, $k_d$, with little variation observed in rates of association. Additionally, surface immobilization typically results in a reduced $k_d$. In this case, the sensor binds the analyte kinetically, irreversibly preventing response to changes in analyte concentration and reuse. Regeneration of the sensor surface is difficult at best. On the other hand, a higher dissociation rate, which would lend itself to a linear and reusable sensor, results in lower affinity and poor sensitivity. Consequently, most biosensors are disposable devices and quantitation is obtained using multiple single-use sensors. Recently, a new reusable biosensor platform which provides simultaneous fluorescence detection and electrochemical control of biospecific binding has been developed.$^{25}$ Biotin was covalently attached to a transparent indium tin oxide electrode, which also served as an integral part of a TIRF flow cell. TIRF was used to monitor biospecific interactions while electrochemical polarization was employed to control the interactions. Antibody–antigen and avidin–biotin interactions both exhibited reversibility over 30 reuse cycles. A generalized TIRF biosensor scheme known as a “sensogram” is shown in Figure 8.

5.2.2.4 Chromatographic Surfaces The application of TIRF has been further expanded for the characterization of chromatographic surfaces to obtain a better understanding of the solute separation mechanism on a molecular level. The microenvironment polarity of chromatographic surfaces has been investigated by TIRF.$^{49,50}$ Hartner et al.$^{49}$ derivatized a fused silica plate with octadecyltrichlorosilane to obtain a C$_{18}$ surface layer. The derivatized plate was optically coupled, with an index matching fluid, to an internal reflection quartz prism. Rangnekar and Oldham$^{50}$ chemically modified a multiple internal reflection element (single-pass parallelepipied 60° bevel angle UV-quartz plate) with octadecylchlorosilane and AquaSil™. Their TIRF optical configuration provided multiple internal reflections (number of reflections = 7) which increased the sensitivity. In both studies, the interfacial molecular environment was probed by pyrene physisorbed onto the modified surface. Pyrene TIRF emission spectra were collected in the presence of overlaying methanol/water mixtures. TIRF provided sufficient selectivity and sensitivity to allow the environment of the interface to be probed by pyrene which was adsorbed from the bulk solution. The percentage of the TIRF signal from the surface-adsorbed pyrene and the bulk-solution pyrene depends on the partition ratio under the conditions and the depth of penetration of the evanescent wave beyond the interface. The vibronic band intensities of pyrene, which are quite sensitive to the surrounding polarity, provided an insight to the polarity of the interior of the C$_{18}$ chains and the chain configuration in the presence of different polar solvents. TIRF anisotropy measurements have led to estimations of the microviscosity of the chromatographic stationary phase$^{51}$ and the orientational dynamics of solutes in a chromatographic stationary phase.$^{52,53}$ The basis of fluorescence anisotropy measurements is that,

**Figure 8 Generalized sensogram for a TIRF biosensor.**
upon excitation of the sample with polarized light, the polarization of the emission intensity is related to the molecular orientation. Since the molecule rotates within its excited state lifetime, the emitted fluorescence is depolarized. The fluorescence depolarization (or anisotropy) measurements disclose information concerning rotational mobility, which in turn is associated with the size and shape of the fluorophore and the viscosity of the surrounding medium.

Rangnekar et al.\(^1\) chemically modified a UV-quartz surface with different silylating reagents to obtain either C\(_1\)-, C\(_3\)-, C\(_8\)- or C\(_{18}\)-modified silica surfaces. TIRF anisotropy data of 1,6-diphenyl-hexatriene were collected on unmodified and modified surfaces in the presence of overlaying solvents covering a range of viscosities. Their results indicate that the adsorption and partitioning mechanisms depend at least partially on the carbon number of the alkyl chain. They estimated the C\(_{18}\) surface microviscosity to be approximately 18 cP.

Wirth and Burbage\(^2\) have derived mathematical relationships for TIRF anisotropy studies of adsorbate reorientation at surface/liquid interfaces. The group examined the reorientation of acridine orange adsorbed on an (octadecyl)silyl)silica surface. In the study, an octadecylsilane (ODS)-derivatized fused silica plate was optically coupled, with a silica index matching fluid, to a trapezoidal internal reflection prism. The thermodynamic equilibrium between the surface-adsorbed acridine orange and aqueous acridine orange was maintained by continuously flowing the solution through a flow cell. The surface acridine orange was excited with light polarized either in-plane or out-of-plane by using an evanescent wave. Fluorescence-domain spectroscopy was used to characterize the fluorescence anisotropy decays of acridine orange. The experiments revealed that the out-of-plane rotations of acridine orange at the ODS/water interface were strongly hindered, while the in-plane rotations gave rise to a double exponential decay of unknown origin. The interpretation was that acridine orange resides at the ODS/water interface. Wirth’s group\(^3\) has also examined the effect of wetting by alcohols on the orientations of C\(_{18}\) chains. The geometry of the probe solute bis-p-(o-methyl)styrlylbenzene used in the study favored preferential alignment with the C\(_{18}\) chains. It was assumed that any changes in the orientational distribution and dynamics of the C\(_{18}\) chains caused related changes in the orientational distribution and dynamics of the probe solute. The results indicate that the C\(_{18}\) chains lie flat on the surface when water is the mobile phase. A small amount of alcohol added to the water causes the C\(_{18}\) chains to become extended towards the surface normal and the chains become random in orientation. But it is likely that wetting has a significantly smaller effect upon the chain orientation.

This article is a survey of the data analysis methods that have been applied to ultraviolet (UV) and visible molecular absorbance and fluorescence measurements. The section after the Introduction reviews the principles of the most widely used types of absorbance and fluorescence measurements. These include steady-state, dynamic and multidimensional measurements. After a brief description of absorption and fluorescence instruments, three classes of data analysis methods for molecular absorbance and fluorescence are described: regression methods, decay analysis and matrix factorization methods. Result validation, software alternatives and future developments are discussed in short sections at the end of the article. A short matrix algebra primer is provided as an appendix to the article.

1 INTRODUCTION

Ultraviolet/visible (UV/VIS) molecular absorbance measurements are among the most widely used spectrochemical methods because they provide nearly universal detection and require modest investments in equipment and user training, except in the case of ultrafast dynamic measurements. UV/VIS molecular fluorescence measurements are less widely used than absorbance methods; relatively few molecules are intrinsically good fluorescers and equipment, maintenance and training for dynamic experiments can be expensive. Despite this, fluorescence measurements are critical in several areas of important research. First, the detection limits of fluorescence are unparalleled by any other method for molecules in solution. Single molecule studies routinely capitalize on this feature. Second, fluorescence emission occurs on the timescale of molecular motions and is thus sensitive to molecular interactions and dynamics. Dynamic fluorescence measurements can be used to measure excited state reaction rates, translational and rotational diffusion coefficients, intramolecular distances, solute–solvent interactions and related parameters. Several fluorophores emit microenvironment sensitive fluorescence which can be correlated to local solvent properties such as polarity, viscosity, pH and potential. These capabilities are the basis of the wide use of fluorescence methods in photochemical, biophysical, and photobiological studies. (Of course, this feature has a dark side. It is a primary source of fluorescence sensitivity.
to matrix effects.) Third, fluorescence is a function of many experimental variables. Experimental variables can be adjusted to avoid known interference or the fluorescence measurement can be made as a function of simultaneous variation in several variables in order to take advantage of numerical methods for analysis in the presence of interference.

This article is a survey of the data analysis methods that have been applied to UV/VIS molecular absorbance and fluorescence measurements. While the name of this Series implies an exhaustive reference that includes the most obscure data analysis procedures, this report is limited to methods that are in wide use or enable analysts to take advantage of advances in instrument technology. Most of the material is presented in two of the seven report sections. The first, section 2, reviews the principles of the most widely used types of absorbance and fluorescence measurements. This section introduces mathematical expressions that describe the data acquired in each type of measurement for which analysis methods will be discussed. These expressions are important because they define the information content of each measurement and provide the basis for deciding which analysis procedure(s) is (are) best suited to recovering the desired information from the data. The reviews also provide brief overviews of the potential applications of each measurement. The second major section is section 4, which organizes data analysis methods for molecular absorbance and fluorescence into three classes. Section 4 also describes the principles and application of the most prominent data analysis methods in each of the three classes. Section 5 is the discussion of result validation for the various analysis classes. It is not as large as sections 2 and 4, but the topic is very important. Despite the best efforts of generations of scientists and statisticians, there is generally an element of subjectivity in data analysis. This is particularly true of measurements comprised of combinations of exponentials, such as dynamic absorbance and fluorescence. It is imperative that data analysis results be evaluated for statistical relevance and stability and bound by confidence intervals whenever possible.

Even the simplest measurement, for example a single sample absorbance and the absorbances of the calibration standards, can be organized into a data set using matrix algebra. Topics such as multicomponent analysis, multichannel (multiple variable) measurements, and curve fitting which involve more complicated data arrangements and operations, would be impossible to discuss without matrix algebra. There are many good tutorials on matrix algebra that will help the reader master the algebra used in this article. The most important ideas to remember are: (1) addition, subtraction and scalar multiplication for vectors and matrices are directly analogous to their scalar counterparts; (2) multiplying by an inverse matrix is analogous to division; (3) most single variable operations, for example differentiation, integration, expansion, have direct analogies to vectors and matrices.

A detailed description of the notation used in this report is given at the beginning of the matrix algebra basics in Appendix I. It suffices here to say that conventional matrix notation and variable names are used wherever possible. For example, boldface Roman and Greek letters represent matrices and vectors. Unfortunately, a uniform and consistent notation scheme is incompatible with some commonly used variable names. For example, the capitalized variable I typically represents light intensity, a scalar quantity. In this article, underlining and italics will distinguish scalar variables and vectors. For example, the intensity of fluorescence is represented by the italicized variable I; a single underline under an italicized variable indicates a related vector quantity, I; and a matrix is indicated by double underlining, I. (It is important to remember that a series of italicized variables and their unitalized counterparts, e.g. S, S, S, s, s, S, are unrelated.) In section 2, boldface also will be applied to the independent variables to help emphasize the order of the measurement. So, I(λ, λ, ψ, t) or I is a single value: the intensity observed after excitation at λ at one λ through polarizer set to angle ψ at t seconds after excitation. I(λ, λ, ψ, t) or I(λ) is a vector: the fluorescence emission spectrum produced by excitation at λ observed through polarizer set at ψ at time t after excitation. I(λ, λ, ψ, t) or I(λ, t) is a matrix: the fluorescence intensity produced by excitation at λ monitored as a function of λ and t through a polarizer set at ψ. This can go on, but I hope the point is made. Data dispersed in more than three dimensions and N-way matrices are germane to the topic, but the requisite data analysis methods are beyond the scope of this article. There is only a brief discussion of three-way fluorescence data in section 4.4.3. The other cases of unconventional notation arise when a single variable name is commonly used to define two entities. Some common variable names have been changed in order to avoid multiple definitions for variables wherever possible. For example, the variable r commonly represents both the distance between donor–acceptor pairs in energy transfer measurements and the fluorescence anisotropy. In this article, d denotes the interatomic distance to distinguish it from the fluorescence anisotropy. Despite these steps, multiple variable definitions could not be completely avoided. The most glaring example is the use of the letters i, j, k, l, m, n, p and q to represent element labels in vectors and matrices and counters in sums and products in addition to their use as variables.
2 PRINCIPLES OF ULTRAVIOLET/VISIBLE MOLECULAR ABSORBANCE AND FLUORESCENCE MEASUREMENTS

2.1 Ultraviolet/Visible Absorbance Data

2.1.1 Steady-state Ultraviolet/Visible Absorbance Data

The energy level spacing of many molecules, especially large organic molecules, is such that they absorb light in the UV to visible wavelength range, that is ~200–800 nm. This is illustrated in the Jablonski diagram depicted in Figure 1. The intensity of light absorbed by a sample is an extensive property that depends on the electronic energy level spacing in the chromophore and the number of chromophores the light beam encounters. Specifically, Beer–Lambert’s law relates the intensity of light absorbed to the concentration of solution species, as shown in Equations (1) and (2):

\[ I_T(\lambda_{ex}) = I_I(\lambda_{ex})e^{-\varepsilon(\lambda_{ex})bc} \]  
\[ A(\lambda_{ex}) = \log \frac{I_I(\lambda_{ex})}{I_T(\lambda_{ex})} = \varepsilon(\lambda_{ex})bc \]

where \( I_I \) is the incident light intensity, \( I_T \) is the transmitted light intensity, \( \varepsilon(\lambda_{ex}) \) is the molar absorptivity at a specific wavelength, \( b \) is the beam pathlength through the sample, \( c \) is the concentration of the chromophore and \( A \) is the absorbance. The absorbance spectrum, \( A(\lambda_{ex}) \), is a plot of the absorbance as a function of excitation wavelength. The absorption wavelength reflects the energy of the excited state. The spectrum band structure reflects the vibronic band spacing of the chromophore excited state. Figure 2 depicts the absorbance spectra of two forms of phytochrome, a photoreceptor that regulates plant growth and development. The biologically active far-red-light absorbing form is reversibly photogenerated from the red-light absorbing form.

As a consequence of Beer’s law, the majority of absorbance data is acquired as an indicator of concentration. Hence, the goal of most absorbance data analysis is to use the dependence of the absorbance on the analyte concentration for quantitation. UV/VIS molecular absorbance spectra of molecules in liquid solution near room temperature are typically broad. Spectral overlap, absorption by other sample components and matrix effects that produce deviations from Beer’s law all complicate quantitation.

2.1.2 Dynamic Ultraviolet/Visible Absorbance Data

Several experimental procedures generate dynamic absorbance data. As in the case of steady-state data, the goal of such analyses is to quantify the components of a system, but with respect to time. These experiments monitor reaction progress, so the goal of the data analysis is isolation of individual component spectra and evaluation of system kinetics. Kinetic analysis generally consists of identifying a model that describes the reaction and determining the rates of the various processes that occur within the system.

In the simplest versions of these experiments, absorbances at a single wavelength are measured as a function of time. Absorbance spectrometers based on multichannel detectors are available commercially at modest prices, making spectra measured as a function of time a common alternative data format. Multichannel spectrometers can be used to monitor chromatographic and electrophoretic separations or, more commonly, to study kinetic behavior. The mixing apparatus, source pulse rate and detector rise time define the measurement timescale.

 absorptions and fluorophores can be excised with room time.
A spectrometer based on a deuterium lamp and photodiode array can monitor reactions exhibiting millisecond or slower kinetics. Stopped-flow methods, xenon-flash lamps and intensified photodiode arrays can monitor microsecond kinetics. Pulsed-laser techniques such as differential transient absorption can monitor the time-dependent behavior of faster processes. For instance, picosecond dynamics can be monitored by measuring the difference in the absorbance of the unexcited sample and the sample at some time after excitation by a pump laser pulse. Monitoring this difference as a function of the delay between the pump beam and probe beam produces a record of the changes in the absorption as a function of time on the scale of the delay. Figure 3 depicts the transient absorption spectra of the visual pigment rhodopsin.

In multichannel kinetic measurements, the data set acquired is an absorbance–time matrix. Beer’s law defines the components of this matrix. Assuming unit pathlength, the matrix elements are the sums of the products of molar absorptivities of the sample components at the observation times, as shown in Equation (3).

\[ \Delta = \sum_k x_k^T C_k = EC^T \]  

(3)

Each column of \( \Delta \) is the absorbance spectrum of the sample at a single observation time. Each row is the time course of the absorbance at a single wavelength. Each column of \( E \) consists of the molar absorptivities of one sample constituent at all the wavelengths monitored during the measurement. Each column of \( C \) stores the ground-state concentrations of one sample constituent as a function of the observation times. In the case of transient absorbance measurements, the columns of \( C \) are the excited-state concentration profiles. The goal of kinetic analysis is to isolate the time profiles of the sample constituents, \( C \), and determine the kinetic rates that describe the time dependence of the concentrations.

### 2.2 Fluorescence Intensity Measurements

#### 2.2.1 Steady-state Intensity Measurements

When rigid molecules that have extended conjugated \( \pi \)-electron systems are photoexcited, many of the vibrational and rotational deactivation mechanisms that depopulate excited states are not available. Such molecules relax via photon emission. In conjugated organic molecules, fluorescence is usually observed during transitions from the first excited to ground singlet states, as depicted by bold solid lines in Figure 1.

The intensity of fluorescence emission is a function of several measurement variables and conditions; the most crucial are the excitation source properties. First, the wavelength of the excitation must correspond to the electronic energy level spacing of the fluorophore (Figure 1) in order to produce the excited state. Fluorescence emission is a random process that is driven by photoexcitation. A differential equation describes the rate of fluorophore excitation and relaxation characterizing the time dependence of the number of excited states in a homogeneous population of fluorophores, as shown in Equation (4).

\[ \frac{dz}{dt} = e - k_t z \]  

(4)

where \( z \) represents the instantaneous concentration of excited fluorophores, \( e \) is the rate of excitation, and \( k_t \) is the first-order rate constant describing excited state deactivation. The relaxation rate is actually a combination of the rates of all processes that deactivate the excited state, \( k_t = k_t^0 + k_{nr} \), where the nonradiative processes (see Figure 1) have been collected into a single term, \( k_{nr} \).
time dependence of the emission also depends on the time course of the excitation beam, \( e = I(t) \). The observed intensity is the convolution of the excitation beam and the impulse response, i.e. system response to excitation by an infinitely narrow pulse. In the case of single fluorophores in dilute isotropic solution the impulse response function is generally a monoexponential decay. Equation (5) shows:

\[
I(t) = I_0 \exp(-t/\tau_f)
\]

where \( V \) is the volume of solution from which fluorescence can be derived from the intensity of the light absorbed by the molecule, as shown in Equation (7)

\[
I_A = I_t - I_r = I_t(1 - e^{-bc/\tau_f})
\]

The fluorescence quantum yield, \( \phi_f \), is the number of photons emitted per photon absorbed. Equation (8) shows:

\[
I(t) = \phi_I I_A \exp(-t/\tau_f)
\]

The intensity of fluorescence, \( I_t \), is proportional to the incident light intensity at low absorbances \( A < 0.050 \). The excitation spectrum \( I(t) \) illustrates the dependence of the emission intensity on excitation wavelength. The excitation spectrum has the same profile as the absorbance spectrum when it is corrected for instrument response and measurement conditions, yet it is measured at concentrations well below the detection limits of absorption spectrometers. The excitation spectrum of perylene is pictured in Figure 4.

In steady-state measurements, the excitation function is constant, \( e(t) = I(t)k_Ac \). The ground state fluorophore concentration, \( c \), is unchanged by the production of excited states at rate \( k_A \). The constant (except for noise) source intensity produces a steady pool of excited fluorophores. The number of excited fluorophores reaches a constant value as a dynamic equilibrium between excited state production and deactivation is reached. The solution of Equation (4), shown in Equation (6), in this case is proportional to

\[
z(t) = \frac{k_A c}{k_t + k_{nt}}
\]

Another expression for the steady-state fluorescence can be derived from the intensity of the light absorbed by the molecule, as shown in Equation (7)

\[
I_A = I_t - I_r = I_t(1 - e^{-bc/\tau_f})
\]

The fluorescence quantum yield, \( \phi_f \), is the number of photons emitted per photon absorbed. Equation (8) shows:

\[
I(t) = \phi_I I_A \exp(-t/\tau_f)
\]

Figure 4 Uncorrected fluorescence excitation spectrum of perylene in ethanol monitored at 437 nm.

Figure 5 Uncorrected fluorescence emission spectrum of perylene in ethanol excited at 415 nm.
Consequently, spectral overlap is a primary limitation to accurate fluorescence analysis of multicomponent samples. In synchronous spectra, the fluorescence intensity is monitored as both the excitation and emission wavelength (monochromator) settings are changed. The resulting spectra can have reduced bandwidths and improved selectivity, as the synchronous spectrum in Figure 6 illustrates. Derivative spectra can also exhibit narrowed bandwidths. However, the resolution enhancement can be offset by the concomitant decrease in the signal-to-noise ratio.

As in the case of absorbance measurements, analyte quantitation is the goal of most steady-state fluorescence intensity analysis. When the species of interest is not intrinsically fluorescent, fluorescent groups can be attached covalently or noncovalently, then used to locate and/or quantitate the analyte. In most routine analyses, the analyte concentration is proportional to a single fluorescence intensity value. The ratio of the fluorescence measured at two wavelengths also can be correlated to analyte concentration. This approach is not as widely used as the single channel method, but has the additional benefit of reducing measurement vulnerability to source fluctuations and matrix effects. Calibration and quantitation using the entire excitation or emission spectrum, which can permit simultaneous multicomponent analysis and contaminant detection, is gaining acceptance but is not widely practiced.

### 2.2.2 Time-resolved Intensity Measurements

The kinetics of photoinduced processes monitor dynamic processes that occur on the timescale of the fluorophore lifetime or the effect of the solvent on fluorophore dynamic properties. Probe methods are widely used to characterize macromolecules such as surfactants, polymers, proteins, nucleic acids and lipids.

In time-correlated single photon counting and other time-resolved emission decay measurements, the emission intensity observed at the detector is the convolution of the excitation pulse and impulse response, as shown in

**Figure 6** Fluorescence emission spectra (excitation wavelength fixed at 335 nm) and fluorescence synchronous spectra (excitation wavelength scanned from 300 nm to 475 nm) of an anthracene/perylene mixture in ethanol.

**Figure 7** Time-resolved emission decay of 2,6-toludinynaphthalene sulfonate in phospholipid vesicles: (a) excitation profile; (b) emission decay; (c) simulated decay; (d) residuals. (Reproduced by permission of the Biophysical Society from Easter et al.)
Equation (10)

\[ I(\lambda_{ex}, \lambda_{em}, t) = k_0 \left[ I(\lambda_{ex}, t) * z_0(\lambda_{ex}) \zeta(\lambda_{em}) e^{-t/\tau_i} \right] = k_0 \left[ \sum_s I(\lambda_{ex}, s) * z_0(\lambda_{ex}) \zeta(\lambda_{em}) e^{-(t-s)/\tau_i} \right] \]

where \( z_0 \) now equals 2.303 A (\( \lambda_{ex} \)). Figure 7 illustrates the time-dependence of 2,6-toludinylnaphthalene sulfonate in phospholipid vesicles after pulsed excitation.\(^{(25)}\)

### 2.2.3 Frequency-domain Intensity Measurements

The frequency-domain intensity decay measurement produces the Fourier transform of the time-domain measurement using a sinusoidally modulated excitation beam.\(^{(26)}\) The signal observed at the detector in a frequency-domain measurement of a single fluorophore in ideal solution is the convolution of the impulse response and excitation function. Specifically, Equation (11) shows

\[ I(\lambda_{ex}, \lambda_{em}, t) = k_0 \left[ I(\lambda_{ex}, t) + p_{\lambda_{ex}} \sin wt \right] \times \left[ z_0(\lambda_{ex}) \zeta(\lambda_{em}) e^{-t/\tau_i} \right] = I(\lambda_{ex}, \lambda_{em})[1 + m_{\lambda_{ex}} \sin(wt - \psi_{\lambda_{ex}})] \]

at each frequency, \( w \). The emission oscillates at frequency \( w \), but is demodulated and lags behind the oscillating excitation beam (Figure 8a). The phase lag, \( \psi_{\lambda_{ex}} \), and relative modulation, \( m_{\lambda_{ex}} / p_{\lambda_{ex}} \), of the emission at several frequencies can be related to the impulse response through the Fourier transform. Equation (12) shows

\[ z(t) = z_0(\lambda_{ex}) \zeta(\lambda_{em}) e^{-t/\tau_i} \Longleftrightarrow z_0(\lambda_{ex}) \zeta(\lambda_{em}) \times \frac{1/\tau - iw}{1/\tau^2 + w^2} = z_0(\lambda_{ex}) \zeta(\lambda_{em}) m_{\lambda_{ex}} e^{-iw} \]

\[ = q + ip = \tilde{z}(w) \]

The vectors \( \psi \) and \( m \) represent, respectively, the phase lags and demodulation factors of the decay at the excitation modulation frequencies, \( \omega \), used to acquire the data. The cosine and sine transforms of the decay at the measurement frequencies are the elements of \( \mathbf{p} \) and \( \mathbf{q} \), respectively. Figure 8(b) and 8(c) illustrates two representations of the frequency-dependent decay of perylene emission. The first is a plot of the phase and modulation versus the modulation frequency. The second is a plot of the Fourier coefficients, \( q \) and \( p \), versus modulation frequency.

### 2.2.4 Multiexponential Decays

Before leaving this brief introduction to dynamic measurements, a few words about multiple fluorophores and fluorophores in nonideal solutions are in order here. When a fluorophore is solvated by a nonideal solution, fluorophores in nonideal solutions are in order here.

---

**Figure 8** Frequency-domain measurement of perylene emission. (a) Oscillating excitation and demodulated, phase (\( \Phi \)) retarded perylene emission. (b) Phase and modulation of perylene emission as a function of excitation modulation frequency. (c) Fourier coefficients of decay as a function of excitation modulation frequency.
excited state increases. If the fluorophore is solubilized in a microheterogeneous environment, e.g. in a biomembrane or surfactant aggregate, the fluorophore may decay at a range of rates if the variations in the fluorophore environments lead to differences in relaxation rates. In this case, a distribution of lifetimes will describe the emission decay as shown in Equation (13)

$$I_f(t) = \sum_{\tau} \alpha(\tau)e^{-t/\tau}$$

where the pre-exponential factor, $\alpha(\tau)$, constitutes the lifetime distribution. Figure 9 illustrates the lifetime distribution and time-dependence of the emission of dilute concentrations of pyrene in microheterogeneous media such as lipids or surfactants after pulsed excitation.\(^{(27)}\)

The monoexponential decay that has the same average decay constant is shown for comparison. It is often the case that first-order kinetics describe the decay and interactions of the fluorescent components of a sample. If a sample contains $n$ components, Equation (4) becomes Equation (14)

$$\frac{d}{dt} z_j = k_{1j} \cdots k_{nj} z_j + e \cdots$$

$$z_n = k_{n1} \cdots k_{nn} z_n$$

$$= Kz + eI$$

The elements of $z$ are the instantaneous concentrations of the excited fluorophores. The diagonal elements of $K$ (the transfer matrix) are the decay constants of the sample components, the off-diagonals are the rates of conversion between the excited sample components. The vector function $eI$ is the driving or input function that produces the excited-state populations, i.e. the laser pulse in time-resolved measurements.

For time-domain experiments, assuming excitation powers well below saturating intensities, the solution of this system of equations is a time-dependent vector of excited state concentrations. Equation (15) shows

$$z(t) = We^{At}W^{-1}z_0$$

where $W$ is a matrix whose columns are the eigenvectors of the matrix $K$ (i.e. $KW = WA$), $e^{At}$ is a matrix that has the exponential of the product of the observation time and decay constants (eigenvalues of $K$) on the diagonal, and $z_0$ is a vector of the initial concentrations of the emitting excited states. Each component of this solution is a combination of the exponentials that decay at rates given by elements of $A$. Figure 10 is a simulation of the time-dependence of pyrene monomer and excimer emission after pulsed excitation.\(^{(28)}\)

Writing this solution at all observation times in matrix format yields Equation (16):

$$Z^T = W\Gamma L^T$$

where the columns of $Z$ and $L$ are the decay profiles of the sample components and their constituent exponentials, respectively. The diagonal elements of $\Gamma$ are concentration factors. When the fluorophores do not interact in the excited state, the $K$ is diagonal and $W$ is an identity matrix. Each component decays monoexponentially with a decay rate equal to the inverse excited state lifetime. When there is an excited state reaction, $K$ is not diagonal nor is $W$ an identity matrix. Each is a combination of $n$ components

where a dipole. Anisotropy is a measure of the average angular orientation of molecules in the solution. The fluorescence anisotropy decay is a function of many sample properties including the fluorophore shape and size, the solvent viscosity and temperature and fluorophore dynamics such as rotations, torsional motion and conformational changes. Consequently, time-dependent anisotropy measurements are a source of information regarding molecular structure and photophysical processes that affect molecular structure.

The emission polarization can be measured using the anisotropy, r, or the polarization, P. These parameters are defined in Equations (17) and (18):

\[
r = \frac{I_1 - I_\perp}{I_1 + 2I_\perp} = \frac{I_1 - I_\perp}{I_1}
\]

\[
P = \frac{I_1 - I_\perp}{I_1 + I_\perp}
\]

where \(I_1\) and \(I_\perp\) are the intensities of fluorescence observed through parallel and perpendicular polarizers, respectively. The two measurements are completely analogous but it is more convenient to use the anisotropy in the analysis of multicomponent systems because r is a simple weighted average of the component anisotropies, as shown in Equation (19)

\[
r = \sum_k \alpha_k r_k
\]

where \(\alpha_k\) is the fraction of the steady-state intensity emitted by the \(k\)th sample component.

When the fluorophore position is immobilized, the anisotropy is a measure of the average angular displacement of the emission dipole from the absorption dipole.\(^{20}\) When the fluorophore is in motion, the polarization of the emission depends on the rate at which the molecules rotate away from their initial configuration. The steady-state anisotropy is the time-average of the time-dependent anisotropy (see the next section). In the case of spherical molecules, the steady-state anisotropy is given by Equation (20)

\[
r = \frac{r_0}{1 + \tau_1/\tau_c} = \frac{r_0}{1 + 6D\tau_c}
\]

In this expression, \(r_0\) is the limiting or fundamental anisotropy (the anisotropy observed in the absence of any depolarization), \(\tau_1\) is the fluorescence lifetime (the average lifetime of the excited state after photoexcitation), \(\tau_c\) is the rotational correlation time (the inverse of the fluorophore rotational rate multiplied by six). \(D\) is called the fluorophore rotational diffusion coefficient. The rotational diffusion coefficient can be related to the solvent viscosity and molecular volume by the Stokes–Einstein equation, as shown in Equation (21):

\[
6D = \frac{RT}{\eta V}
\]

where \(R\) is the gas constant, \(T\) is the temperature, \(\eta\) is the macroscopic solvent viscosity and \(V\) is the molar volume of the fluorophore.

### 2.3.2 Time-resolved Anisotropy Measurements

Time-resolved anisotropy measurements depend on the fluorophore volume, solvent viscosity and temperature just as steady-state measurements do. Investigators have used dynamic anisotropy measurements in a variety of studies. Some examples include measuring solute rotation in biomembranes\(^{30}\) and polymers, monitoring protein folding,\(^{31}\) studies of ligand binding to macromolecules\(^{32}\) and solute interaction with chromatographic surfaces.\(^{33}\)

In the case of spherical molecules, the anisotropy decay is monoexponential as shown in Equation (22)

\[
r(t) = r_0e^{-t/\tau_c}
\]

The decay constant is the inverse rotational correlation time which is the inverse of six times the rotational diffusion coefficient (see Equations 20 and 21). Since the depolarization depends on the shape of the molecule, substantial efforts were made to extend the theoretical descriptions to include nonspherical molecules so that shape and orientational information could be recovered from polarization measurements. The most complete theoretical treatments accomplish this by solving a generalized rotational diffusion equation and calculating the intensity of fluorescence emission in the directions parallel and perpendicular to the excitation electric vector.\(^{34}\) These treatments predict that the fluorescence anisotropy decay of an asymmetric molecule is comprised of five exponential components. The generalized
time-dependent anisotropy is given by Equation (23)

\[ r(t) = 0.3[4z_{12}e^{-3D_1+D\Delta} + 4z_{23}e^{-3D_1+D\Delta}] \\
+ 4z_{31}e^{-3D_2+D\Delta} + (\Phi + \Psi)e^{-6D+2\Delta} \\
+ (\Phi - \Psi)e^{-6D-2\Delta}] \]  

(23)

where \( D_1, D \) and \( \Delta \) are functions of the rotation tensors (rotational coefficients around the molecular axes), \( z_{ij} \), \( \Phi \) and \( \Psi \) are functions of the fluorophore absorption and emission transition moments. Here, the difficult task of analyzing complex exponentials is compounded by the fact that two pairs of the five decay constants are typically close and the fact that individual fluorophores within a single macromolecule can decay and/or rotate independently.\(^{(35)}\) Figure 11 illustrates the time-dependence of perylene anisotropy.\(^{(36)}\) Perylene is a symmetric disk-shaped molecule such that \( D_1 = D_4 \) and \( D_2 = D_3 = D_{1/2} \). Equation (23) reduces to a triple exponential decay.

2.4 Quenching Measurements

2.4.1 Steady-state Quenching Measurements

Quenchers are solutes that attenuate fluorophore emission. Quenching measurements reveal the accessibility of fluorophores to the quencher and thus information about the structure of the medium around the fluorophore.\(^{(83)}\) This approach can used to determine if a chromophore is buried deeply within a macrocycle or extended near the surface.\(^{(37)}\) Quenching measurements can also be used to measure how well a surfactant or other delivery system sequesters molecules from the bulk solvent.\(^{(38)}\)

Quenching mechanisms fall into two primary classes. Static quenchers prevent fluorophores from being excited; dynamic quenchers increase the rate of excited state deactivation through collisional processes. Combinations of both mechanisms can be observed simultaneously in complex media. The dependence of the steady-state fluorescence intensity on quencher concentration in either case is given by Equation (24)

\[ \frac{I_f(0)}{I_f([Q])} = 1 - K_Q[Q] \]  

(24)

\( I_f(0) \) is the intensity of fluorescence at zero quencher concentration, \( K_Q \) is the quencher constant. In static quenching, \( K_Q \) is the equilibrium constant for the complexation reaction between the fluorophore and quencher. In dynamic quenching, \( K_Q \) is the product of the fluorophore lifetime and the biomolecular quenching constant. Static and collisional quenching can be distinguished by dynamic measurements, which will be discussed in the next section.

2.4.2 Time-resolved Quenching Measurements

Lifetime measurements distinguish static and dynamic quenching. In the case of static quenching, the duration of the excited state is unchanged. Only the number of fluorophores being excited is reduced, so the ratio of unquenched to quenched lifetimes is always one. Dynamic quenchers reduce the excited state lifetime and, proportionately, the steady-state intensity. Therefore, the quenching constant indicated by the
ratio of unquenched to quenched lifetimes and the ratio of unquenched to quenched intensities is the same for dynamic quenching. Specifically, Equation (25) shows

\[ \frac{I_t(0)}{I_t([Q])} = 1 + k_q\tau_0[Q] = \frac{\tau_0}{\tau} \]  

(25)

where \(I_t(0)\) and \(\tau_0\) are the intensity of fluorescence and fluorophore lifetime at zero quencher concentration, respectively. Figure 12 illustrates the difference in the intensity and lifetime ratios. Figure 12 shows the Stern–Volmer plots of the quenching of labelled creatine kinase by acrylamide. The lifetime ratios fall on straight lines, indicating collisional quenching. The intensity ratio exhibits the negative curvature, indicating that some of the fluorescent labels are partially sequestered from the acrylamide in the solution.

2.5 Energy Transfer Measurements

2.5.1 Steady-state Energy Transfer Measurements

Excited state energy can be transferred from one molecule (the donor) to another (the acceptor) without photon emission by the donor. This phenomenon occurs through dipole–dipole interactions when the donor emission spectrum overlaps the acceptor excitation spectrum and the molecules are spatially close (\(\sim 50\,\text{Å}\)). Specifically, the rate of Forster energy transfer\(^{40}\) is given by Equation (26)

\[ k_{ET} = (8.71 \times 10^{23})\frac{\kappa^2\phi_I J}{d^6\mu^4}k_D \]  

(26)

The variables \(\phi_D\) and \(k_D\) represent the fluorescence quantum yield and decay time (inverse lifetime) of the donor, respectively. The variables \(d\) and \(\kappa^2\) represent the distance between and relative orientation of the donor–acceptor pair, respectively. The overlap integral \(J\) measures the overlap between the donor emission spectrum and acceptor excitation spectrum. The solvent refractive index is \(n\).

The energy transfer efficiency, \(E\), which is directly related to the donor–acceptor distance, can be measured from steady-state intensities as shown in Equation (27)

\[ E = \frac{D_F^6}{D_F^6 + d^6} = 1 - \frac{I_D([A])}{I_D(0)} \]  

(27)

The Forster distance \(D_F\) is the distance at which the energy transfer rate is equal to the donor decay rate so that 50% of donor molecules relax via energy transfer. \(I_D(0)\) is the fluorescence emission intensity from the donor in the absence of acceptor, \(I_D([A])\) represents donor intensities in the presence of acceptor. The decrease in the donor fluorescence and concomitant increase in acceptor fluorescence as the acceptor concentration is increased is shown in Figure 13.

2.5.2 Dynamic Energy Transfer Measurements

When an energy transfer donor decays in the presence of an acceptor, the decay of the donor is given by Equation (28)

\[ I_D([A], t) \propto \sum_d \alpha_d e^{-t/\tau_d + k_{ET} t} = \sum_d \alpha_d e^{-t/\tau_d}[1+(D_t/d)^6] \]  

(28)

where \(D_{\text{max}}\) is the maximum donor–acceptor distance (see section 2.5.1 for other definitions). If the transfer occurs in viscous solvent (so that the donor-to-acceptor distance is fixed during the excited state lifetime) and the concentration is low (to prevent intermolecular interactions), the vector \(\alpha_d\) represents the distribution distances between the donor and acceptor. The width of the distribution reflects the range of donor-to-acceptor distances in the system. If donor and acceptor are bound to fixed sites, e.g. on a protein, then \(\alpha_d\) represents a series of discrete values.

The energy transfer rate (Equation 26) has been called the spectroscopic ruler.\(^{41}\) Determination of the distance distribution from the donor decay yields mean distances and conformational information regarding the system being monitored. The steady-state and dynamic energy transfer measurements are used to measure the distance between sites in macromolecular systems;\(^{42}\) They are an important source of information regarding
the structure of systems that have not been crystallized or are not amenable to multidimensional nuclear magnetic resonance (NMR) studies.

2.6 Multidimensional Measurements

2.6.1 Steady-state Multidimensional Measurements

A multidimensional data set is produced when the fluorescence emitted by a sample is monitored as a function of the simultaneous variation of two or more measurement variables. The combination of independent measurement variables produces a selectivity increase that is inversely proportional to the correlation in the constituent responses to the individual variables. In many cases, the selectivity increase is sufficient to enable the analyst to resolve the sample constituents, or monitor an analyte in the presence of contaminants.

The most well-known type of steady-state multichannel fluorescence measurement is the intensity measured as a function of the excitation and emission wavelengths. The resulting map has been called the excitation–emission matrix (EEM)\(^{11}\) and the total fluorescence spectrum.\(^{43}\) The EEM of a single component sample is the outer product of the excitation and emission spectra of the fluorophore, as shown in Equation (29)

\[
M(\lambda_{\text{ex}}, \lambda_{\text{em}}) = \gamma x(\lambda_{\text{ex}})y(\lambda_{\text{em}})^T
\]

where \(M\) represents the EEM, \(x\) the fluorophore excitation spectrum and \(y\) the fluorophore emission spectrum. The scalar \(\gamma\) is a concentration dependent proportionality constant.

The EEM of a dilute multicomponent sample is the sum of the \(K\) EEMs, \(M_k\), of the individual fluorophores that comprise the sample. Equation (30) shows

\[
\mathbf{M} = \sum_{k}^{K} \mathbf{M}_k = \sum_{k}^{K} \gamma_k \mathbf{x}_k \mathbf{y}_k^T = \mathbf{X} \mathbf{Y}^T
\]

The excitation and emission spectra of the sample components are stored in the columns of matrices \(\mathbf{X}\) and \(\mathbf{Y}\), respectively. An isometric plot of a mixture of anthracene and perylene is shown in Figure 14.

2.6.2 Time-resolved Multidimensional Intensity Measurements

Multichannel acquisition of dynamic data also produces selectivity increases. All of the experimental variables discussed here, \(\lambda_{\text{ex}}, \lambda_{\text{em}}, \varphi_{\text{ex}}, [O]\), and \([A]\) can be combined with time, or equivalently excitation modulation frequency, to produce multidimensional data sets.

For example, the emission-time resolved decay matrix, \(\mathbf{D}\), is the sum of the outer products of the component emission spectra, \(\gamma_i\), and intensity decay profiles, \(\mathbf{z}_i\), as shown in Equation (31)

\[
\mathbf{D} = \sum_{i}^{L} \gamma_i \mathbf{z}_i^T = \mathbf{Y} \mathbf{Z}^T
\]

In dilute solutions of fluorophores that do not interact (\(\mathbf{K}\) in Equation 14 is diagonal), the decay profiles are pure exponentials, \(\mathbf{I}\), scaled by a concentration factor, \(\gamma_m\). The decay constants of these exponentials are the fluorophore decay rates. Equation (32) shows

\[
\mathbf{D} = \mathbf{Y} \mathbf{\Gamma} \mathbf{L}^T
\]

where the concentration factors, i.e. diagonal elements of \(\mathbf{\Gamma}\), are the initial excited state concentrations of the sample components. When the sample fluorophores participate in excited state reactions (see section 2.2.4), the decay of each fluorophore is affected by the decay of the other components. In this case, the decay is a combination of exponentials, reflecting the structure of the photokinetic transfer matrix describing the excited state reaction. Equation (33) shows

\[
\mathbf{D} = \mathbf{Y} \mathbf{\Gamma} \mathbf{L}^T
\]

The columns of the matrix \(\mathbf{W}\) are the eigenvectors of the photokinetic matrix, \(\mathbf{K}\); the diagonal elements of \(\mathbf{\Gamma}\) are concentration factors given by \(\mathbf{W}^{-1} \mathbf{z}_0\) where \(\mathbf{z}_0\) are initial intensities of the emission decays. The decay constants of the exponentials are the eigenvalues of \(\mathbf{K}\). The time-resolved emission-decay matrix of a mimetic photosynthetic porphyrin\(^{43}\) is shown in Figure 15.

Multidimensional data acquisition facilitates analysis of multicomponent samples without separation. This is especially useful in kinetic studies\(^{45}\) because analyses can be performed in the presence of influential sample components. Calibration methods for multidimensional
data sets can provide robust quantitation in spite of the presence of sample contaminants.\(^{12}\)

### 3 INSTRUMENTATION FOR ULTRAVIOLET/VISIBLE MOLECULAR FLUORESCENCE MEASUREMENTS

#### 3.1 Absorbance Spectrophotometer

Absorbance spectrophotometers are available in several configurations. All of them include a light source, wavelength selection device, sample holder and photon detector. Figure 16 is a schematic of a typical apparatus for measuring steady-state absorbance data and monitoring millisecond kinetics at multiple wavelengths. A deuterium lamp provides broadband excitation from 200 to 800 nm. The light transmitted by the sample is collected by optics, dispersed by a spectrograph and focused onto the surface of a photodiode array. Instrument noise in most absorbance spectrophotometers is a combination of detector dark current (zero percent transmittance (0% T) noise), source flicker (frequency dependent (1/f) noise) and signal shot noise. Error from these sources is normally distributed.

#### 3.2 Time-resolved Spectrofluorometer

Spectrofluorometers are constructed using many of the same components used to construct absorbance spectrophotometers, but the detector–sample axis is 90° to the source–sample axis to minimize collection of scattered light. The classical time-resolved method is time correlated single photon counting. A high repetition rate laser can acquire an entire decay profile in a few seconds. Figure 17 is a schematic of an instrument equipped to measure steady-state and time-resolved fluorescence. The source depicted is a flash lamp, but pulsed lasers are commonly used in this application. The decay is detected by a gated photomultiplier tube. The monochromator in the detection channel permits the measurement of steady-state emission spectra and wavelength dependent decays. The spectrometer has two emission channels equipped with polarizers (T-format) to enable simultaneous measurement of parallel and perpendicular polarized emission. In this type of instrument, measurement errors are produced by detector dark current and analyte shot noise and source flicker. These noise sources are normally distributed. This contrasts the Poisson distributed errors of time-correlated single photon counting measurements.
3.3 Frequency-domain Spectrofluorometer

Figure 18 is a partial schematic of a versatile instrument for measuring steady-state and frequency-domain fluorescence. The source, a xenon arc lamp, is modulated at rates up to 250 MHz by a Pockels cell. The reference excitation beam and sample emission are detected by photomultiplier tubes. These signals are acquired by modulating the gain of both detectors at a frequency close, but not equal to, the source modulation frequency. When this cross-correlation frequency mixes with the signal, the signal carrier frequency is reduced to the difference in the source and detector frequencies. The monochromator in the detection channel permits the measurement of steady-state emission spectra and wavelength-dependent decays. The spectrometer has two emission channels equipped with polarizers (T-format) to enable simultaneous measurement of parallel and perpendicular polarized emission. This instrument measures the modulation ratio and phase lag of the emission relative to those of the excitation. Source flicker, radiofrequency pick-up (from synthesizer harmonic noise), synthesizer phase noise and detector dark current are the significant sources of error in this instrument. These sources are normally distributed.

4 DATA ANALYSIS OF ULTRAVIOLET/VISIBLE MOLECULAR ABSORBANCE AND FLUORESCENCE MEASUREMENTS

4.1 Classification of Data Analysis Methods

There are many similarities in the data types and mathematical expressions outlined in section 2. Consequently, three classes of procedure provide most analysis for absorbance and fluorescence data. To recover sample information from steady-state data, we need programs that model the relationship between the spectral property...
(I_t, r, etc.) and the sample property of interest ([c], V, etc.). The model then can be used to predict the properties of unknown samples. This is the function of regression methods, which are discussed in section 4.2. In dynamic measurements, the sample properties of interest are related to the decay constants or pre-exponential factors. Therefore, decay analysis methods, discussed in section 4.3, are needed to analyze dynamic data. The multivariate data sets, steady-state and dynamic, can be factored into the responses of the sample components. In some cases, the resolved responses will require additional analysis, e.g. decay analysis. Matrix factorization methods are discussed in section 4.4. Prototypical procedures from each of these classes and the primary concerns of the analyst applying them to absorbance and fluorescence data will be discussed in the following sections.

4.2 Regression Methods

4.2.1 Linear Least Squares Regression

When the ideal (noise-free) instrument response of a sample is a known (or suspected) to be a linear function of a single experimental (independent) variable, the parameter values that define the response model can be determined by linear least squares regression (LLSR). The measured response, \( g \), to changes in the experimental variable, \( f \), is the combination of a simulated response, \( s \), and measurement error \( \xi \). A single coefficient, \( \beta \), defines the contributions of the variable to the simulated response. In general terms, this relationship is given by Equation (34)

\[
g = s(\beta, f) + \xi \tag{34}
\]

where \( g, s \) and \( \xi \) are \( N \) element vectors. The values of the independent variable are the \( N \) elements of the vector, \( f \), and \( \beta \) is a scalar. For the sake of a more concrete discussion, let us consider Equation (34) a model of a static quenching study (cf. Equation 24). The quencher concentration is the independent variable, \( f \). The ratio of fluorescence intensities in the absence and presence of the quencher is the measured response, \( g \). The quenching constant is \( \beta \).

There are several equivalent formalisms for describing the principles of least-squares methods. The discussions that follow are close to those given by Scales.\(^{(47)}\). The simulation, \( s \), fits the instrument response, \( g \), in the least-squares sense when the parameters, \( \beta \), minimize the residuals. The residuals are measured by the sum of the squared differences between the response and the simulation, i.e. \( \rho = \sum_n \varepsilon_n^2 \). This sum is minimized when its first derivative with respect to \( \beta \) is zero, as shown in Equation (35)

\[
\frac{\partial \rho}{\partial \beta} = \frac{\partial}{\partial \beta} [g - s(f, \beta)]^T [g - s(f, \beta)] = 0 \tag{35}
\]

Least squares parameters that meet this criterion have the highest probability of being the correct value, i.e. producing a simulation that fits the instrument response. The distribution of simulated responses around the experimental response reveals the inverse relationship between the experimental error and coefficient probability. Notice that \( p(\beta) \) increases as the residuals decrease, as shown in Equation (36)

\[
p(\beta) \propto \exp \left\{ \frac{1}{2} \sum_{n=1}^{N} \frac{g_n - s_n(f, \beta)}{\sigma_n}^2 \right\} \tag{36}
\]

The variable \( \sigma_n \) denotes the standard error in the \( n \)th (of \( N \)) measurement of \( g \), i.e. the intensity ratio in our quenching example. Equation (36) reveals why it is so important to ensure that residuals are drawn from a normal distribution when applying least-squares methods. If the residuals are not normally distributed, least-squares parameters will not have the highest probability of representing the data accurately.

The parameter, e.g. quenching constant, which minimizes the residuals, is determined using Equations (37–39):

\[
p(\beta) = \sum_{n=1}^{N} \varepsilon_n^2 = \xi^T \xi = (g - f\beta)^T (g - f\beta)
\]

\[
= g^T g - 2\beta^T f^T g - \beta^2 f^T f \tag{37}
\]

\[
\frac{\partial p}{\partial \beta} = -2(f^T g + f^T f\beta) = 0 \tag{38}
\]

\[
\hat{\beta} = (f^T f)^{-1} f^T g \tag{39}
\]

The circumflex (\( \hat{\cdot} \)) indicates that \( \hat{\beta} \) is an estimate. Remember that \( f^T f \) and \( f^T g \) are scalar values. They are more familiar than they look. If \( g \) and \( f \) were written as mean-centered vectors, i.e. replaced by \( \bar{g} \) and \( \bar{f} \), respectively, and expanded as sums rather than dot products, Equation (39) would be identical to Equation (40), the formula taught to undergraduates for calculating the slope of a line.\(^{(48)}\)

\[
\hat{\beta} = \frac{N \sum_{n} f_n g_n - \sum_{n} f_n \sum_{i} g_n}{N \sum_{n} f_n^2 - \left( \sum_{n} f_n \right)^2} \tag{40}
\]

4.2.2 Multiple Linear Regression

Multiple linear regression (MLR)\(^{(20)}\) is the extension of LLSR to the analysis of the responses of several samples to several independent variables. The regression determines the values of parameters that model the dependence of the response on experimental values. The
The validity of the model embodied in F traditionally discussed in statistics tutorials. The values of \( (\superscript{-} ) \) emphasize the fact that solving for the predictor matrix is written as a special inverse of fluorescence intensities at \( K \) wavelengths, the concentrations of the components can be recovered. In the following section, measured response, \( G \), the experimental variable, \( F \), the coefficients, \( B \), and measurement error \( \Xi \) are the matrix counterparts of these quantities in section 4.2.1. Think of \( G \), \( S \) and \( \Xi \) as being constructed by arranging the \( N \) element responses for \( M \) samples into a table (matrix). \( F \) must be an \( N \times K \) matrix and \( B \) must be a \( K \times M \) matrix in order to estimate \( G \).

MLR consists of two steps: calibration and quantitation. Calibration consists of measuring the response of standards or samples that can be assayed reliably using alternative methods. In matrix format the calibration model is given by Equation (41)

\[
G_{\text{std}} = FB_{\text{std}} + \Xi \tag{41}
\]

In the steady-state fluorescence example, \( G \) is the matrix of fluorescence intensities at \( K \) or more wavelengths, \( B \) is the matrix of concentrations and \( F \) a matrix of spectral profiles.

In the calibration step, the predictor matrix, \( F_{\text{MLR}} \), is calculated from \( G_{\text{std}} \) and \( B_{\text{std}} \), as shown in Equation (42)

\[
F_{\text{MLR}} = B_{\text{std}}G_{\text{std}}^T(G_{\text{std}}G_{\text{std}}^T)^{-1} \tag{42}
\]

The predictor matrix is written as a special inverse (superscript minus) to emphasize the fact that solving for \( B \) in Equation (41) is the inverse of regression problems traditionally discussed in statistics tutorials. The values of \( F_{\text{MLR}} \) calculated by Equation (42) minimize the sum of squares of the elements of \( \Xi \).

In the quantitation step, the properties of a sample response, e.g. component concentrations, are determined using \( F_{\text{MLR}} \). Equation (43) shows

\[
\hat{B}_{\text{sample}} = F_{\text{MLR}}G_{\text{sample}} \tag{43}
\]

The validity of the model embodied in \( F_{\text{MLR}} \) is measured by the sum of squares of the prediction error, \( \sigma_{\text{PRESS}} \). The prediction error depends on how well \( F_{\text{MLR}} \) reproduces the values of the calibration set, as shown in Equations (44) and (45)

\[
\hat{B}_{\text{std}} = F_{\text{MLR}}G_{\text{std}} \tag{44}
\]

\[
\sigma_{\text{PRESS}} = \sum_{m=1}^{M} \sum_{k=1}^{K} [ (B_{\text{std}})_{km} - (\hat{B}_{\text{std}})_{km} ]^2 \tag{45}
\]

MLR calibrations perform well under ideal conditions. For multivariate spectral measurements a calibration (standard) set is ideal when it is free of interfering contaminants, matrix effects, interactions between standards, severely overlapped standard spectra and has a good signal-to-noise ratio. The method can be used for simultaneous determination of sample components, but it is usually applied with other regression methods because it is less effective when the component spectra are strongly overlapped.

4.2.3 Principle Components Regression and Partial Least Squares Projection

MLR is called a ‘hard’ modeling technique because it establishes a correlation between experimental responses and sample properties, i.e. physically observable quantities. MLR incorporates all the information in the calibration set, including measurement error and contaminants, into the calibration matrix. Soft modeling methods such as principal components regression (PCR) and partial least squares (PLS) minimize these limitations of MLR by transferring information to the prediction matrix, \( F^{-} \), more selectively.

All data matrices can be expressed as combinations of orthonormal basis vectors or factors, as shown in Equation (46)

\[
G = U\Sigma V^T = QV^T \tag{46}
\]

The columns of \( V \) summarize the variance, i.e. collect the shapes, distributed along the rows of \( G \). The first column of \( G \) summarizes all the variance of \( G \), so it is similar to the average of the rows of \( G \). The second column of \( V \) summarizes all the variance not captured by the first column of \( V \). Consequently, it is orthogonal (completely uncorrelated) to the first. This successive extraction of uncorrelated vectors continues until all the variance of \( G \) is captured. The rows of \( Q \) are called scores because they reflect how important each column of \( V \) is to each row of \( G \). The number of columns of \( V \) required to describe the rows of \( G \) is the rank of \( G \). Ideally, the rank of a spectral matrix is \( K \), the number of components absorbing or emitting photons. Experimentally, the rank of a matrix will equal the smaller matrix dimension because of measurement error. In this case, the number of components is the pseudorank of the matrix. The first \( K \) columns of \( V \) (primary principal components) describe the spectral response while the rest (secondary principal components) describe the measurement error. Eliminating the contribution of factors associated with measurement error in Equation (46) reduces the measurement error in the matrix.

In PCR, the response matrix, \( G \), is factored into orthogonal basis vectors and scores and the secondary principal components are discarded. The product of the
remaining components is an estimate of $\mathbf{G}$ that contains significantly lower amounts of measurement error, as shown in Equation (47)

$$
\mathbf{G}_{\text{std}} = \mathbf{Q}\mathbf{V}^T
$$

(47)

where the superpositioned curve indicates that the secondary columns of $\mathbf{Q}$ and $\mathbf{V}$ were discarded prior to the calculation of $\mathbf{G}$. Procedures that estimate the pseudorank are discussed in section 5.2. When all vectors $\mathbf{V}$ are used to reconstruct $\mathbf{G}_{\text{std}}$, the PCR and MLR results are identical.

The PCR calibration is based on the same linear model used in MLR, but the predictor matrix is calculated from the scores of the response matrix. The calibration model is shown in Equation (48)

$$
\mathbf{G}_{\text{std}} = \mathbf{Q}\mathbf{V}^T = \mathbf{F}\mathbf{B}_{\text{std}} + \mathbf{\Xi}
$$

(48)

The predictor matrix is calculated from the primary factors of $\mathbf{G}_{\text{std}}$, as shown in Equations (49) and (50)

$$
\mathbf{F}_{\text{PCR}} = \mathbf{B}_{\text{std}}\mathbf{V}^T\mathbf{Q}(\mathbf{Q}\mathbf{Q}^T)^{-1}
$$

(49)

$$
\mathbf{\hat{B}}_{\text{sample}} = \mathbf{F}_{\text{PCR}}\mathbf{G}_{\text{sample}}
$$

(50)

If the calibration standards of the steady-state fluorescence intensity example were collected using very dilute solutions, for example, the PCR prediction error would be lower than the MLR error. The predictor matrix estimated by MLR is an unbiased estimator of $\mathbf{G}_{\text{std}}$ but its elements can have large variances, leading to imprecise predictions. In PCR, the predictor is biased (the values of $\mathbf{F}_{\text{PCR}}$ do not minimize the sum of squares of $\mathbf{\Xi}$), but has a smaller variance and lower prediction error.

PCR constructs the prediction matrix using orthonormal factors of $\mathbf{G}$ calculated to capture the maximum variance of $\mathbf{G}_{\text{std}}$. These factors are calculated without regard to the calibration variables in $\mathbf{B}_{\text{std}}$. PLS methods factor $\mathbf{G}_{\text{std}}$ into orthogonal factors that are maximally correlated to the calibration variables. This approach minimizes the large errors associated with highly correlated calibration variables. Theoretically, the PLS factors are calculated to minimize the prediction error rather than the residuals of $\mathbf{G}_{\text{std}}$, as shown in Equation (51)

$$
\mathbf{\hat{G}}_{\text{std}}^T = \mathbf{T}\mathbf{C}^T
$$

(51)

$$
\mathbf{B}_{\text{std}}^T = \mathbf{T}\mathbf{\hat{B}}^T
$$

(51)

Keep this straightforward principle in mind because the PLS algorithm is more difficult to understand than the MLR or PCR algorithms. The connection between the form of the predictor matrix and the calibration results is not obvious.

The following algorithm is called the PLS kernel algorithm. It is especially efficient when the number of responses is large and much larger than the pseudorank (number of variables). After rank estimation, the calculation of $\mathbf{T}, \mathbf{C}$ and $\mathbf{P}$ consists of three steps that are repeated until the factors needed to reconstruct $\mathbf{G}_{\text{std}}$ and $\mathbf{B}_{\text{std}}$ have been determined. (Note: it was impossible to record the algorithm here without using variables that have other meanings elsewhere in the article. The variables $\mathbf{T}, \mathbf{P}, \mathbf{C}, \mathbf{W}$ and $\mathbf{R}$ have no connection to their meanings elsewhere in the article.)

1. Calculate the basis vector, $\mathbf{t}_1$, of $\mathbf{G}_{\text{std}}$ that is maximally correlated to $\mathbf{B}_{\text{std}}$. It is the most prominent eigenvector of $\mathbf{B}^T\mathbf{G}\mathbf{T}\mathbf{G}^T$ (subscripts dropped), given by Equation (52)

$$
\mathbf{B}^T\mathbf{G}\mathbf{T}\mathbf{G}_{\mathbf{t}_1} = \mathbf{t}_1\lambda_{11}
$$

(52)

where $\lambda_{11}$ is the eigenvalue of $\mathbf{G}^T\mathbf{G}_{\mathbf{t}_1}$, called the PLS kernel matrix.

2. Calculate $\mathbf{p}_1$ and $\mathbf{c}_1$, shown in Equations (53) and (54), which are the scores of the rows of $\mathbf{B}_{\text{std}}$ and $\mathbf{G}_{\text{std}}$ with respect to $\mathbf{t}_1$.

$$
\mathbf{p}_1 = (\mathbf{t}_1^T\mathbf{B}^T)(\mathbf{t}_1^T\mathbf{t}_1)^{-1}
$$

(53)

$$
\mathbf{c}_1 = (\mathbf{t}_1^T\mathbf{G}^T)(\mathbf{t}_1^T\mathbf{t}_1)^{-1}
$$

(54)

Calculate $\mathbf{w}_1$, the weight of $\mathbf{t}_1$ on the part of the rows of $\mathbf{G}_{\text{std}}$ that are correlated to the columns of $\mathbf{B}_{\text{std}}$. Equation (55) shows:

$$
\mathbf{w}_1 = \mathbf{B}^T\mathbf{G}_{\mathbf{t}_1}
$$

(55)

3. Subtract contributions of $\mathbf{t}_1$ from $\mathbf{G}_{\text{std}}$ and $\mathbf{B}_{\text{std}}$ and return to step 1. Equation (56) shows

$$
\mathbf{R}_{-1} = \mathbf{I} - \mathbf{t}_1^T\mathbf{t}_1^T
$$

(56)

$$
\mathbf{G}_{-1}^T = \mathbf{R}_{-1}\mathbf{G}^T
$$

(56)

$$
\mathbf{B}_{-1}^T = \mathbf{R}_{-1}\mathbf{B}^T
$$

(56)

$\mathbf{R}_{-1}$ is a projection matrix that removes contributions of $\mathbf{t}_1$ from $\mathbf{G}^T\mathbf{G}$ and $\mathbf{B}^T\mathbf{B}$. Subtracting the contributions of $\mathbf{t}_1$ insures that the subsequent columns of $\mathbf{T}$ will be orthogonal to $\mathbf{t}_1$ and each other. The remaining columns (2 through $K$) of $\mathbf{T}, \mathbf{P}, \mathbf{C}$ and $\mathbf{W}$ are determined by repeating steps 1–3 until the number of factors indicated by rank estimation have been determined.

The predictor matrix is calculated from the scores of $\mathbf{B}$ and weights of $\mathbf{T}$ on $\mathbf{G}$ and $\mathbf{B}$, as shown in Equation (57)

$$
\mathbf{F}_{\text{PLS}} = \mathbf{W}(\mathbf{P}^T\mathbf{W})^{-1}\mathbf{C}^T
$$

(57)

The correlation between $\mathbf{G}$ and $\mathbf{B}$ reduces the error of prediction in PLS regression compared to PCR and MLR. Equations (58) and (59) show
Figure 19 Regression vectors calculated by (a) MLR, (b) PCR, and (c) PLS from a calibration set consisting of four mixture emission spectra distorted by random noise and simulated baseline drifts. Spectra (d–e) estimated by regressors in (a–c) magnitude differences and PRESS values (inserts) show superiority of PLS in cases of collinear variables and instrument drift.

\[
\hat{B}_{\text{std}} = F_{\text{PLS}} G_{\text{std}}
\]

\[
\sigma_{\text{PRESS}} = \sum_{m} \sum_{k} (\hat{B}_{\text{std}})_{km} - (\hat{B}_{\text{std}})_{km}^2
\]

In the quantitation step, the properties of the sample responses are calculated using \( F_{\text{PLS}} \), as shown in Equation (60)

\[
B_{\text{sample}} = F_{\text{PLS}} G_{\text{sample}}
\]

PLS improves quantitation when the calibration standards deviate from Beer’s law because of matrix effects, instrument variations and contaminants. It is also more robust when the calibration standards are substantially correlated. All of these deviations are likely to be observed in the steady-state fluorescence intensity.

4.2.4 Application of Regression to Absorbance and Fluorescence Data

Regression methods can be used to recover any sample property that correlates the observed response to the experimental variable. For example, the correlation between the carcinogen metabolism and the habits (e.g. smoking) of workers exposed to polynuclear aromatic hydrocarbons has been modeled using MLR.\(^{52}\) Most applications of regression methods in the literature involve simultaneous determination of multiple sample components using multiple wavelength absorbance and fluorescence intensity measurements. Figure 19 depicts the MLR, PCR and PLS regression vectors used to correlate a hypothetical set of mixture spectra to component concentrations. Regression methods have not been widely used by the biochemical/biophysical fluorescence community, though they could be used to calculate apparent viscosity from steady-state anisotropy of spherical probes, quenching constants and donor–acceptor distances. A list of selected applications of regression methods is provided in Table 1.\(^{49,52–67}\)

4.3 Decay Analysis Methods

The development, application and interpretation of decay analysis methods is an active area of research and discussion. The field is dominated by nonlinear least squares and global target analysis. These methods are described in two of the following sections. The maximum

entropy method (MEM) and multivariate frequency-domain decay analysis (MFDA) method are described because they are model-independent in that neither requires the analyst to select a model to describe the decay prior to the analysis.

4.3.1 Nonlinear Least-squares Fitting

Nonlinear least-squares fitting is a very widely used numerical approach to estimating the contribution of user-specified functions or models to experimental data. There are two types of least squares algorithms for determining parameter values when the model is not a linear function of the experimental variables. Gradient methods use the derivatives of the sum of the squared residuals ($\rho$) with respect to the parameters ($\beta$) to identify the minimum in $\rho$. Function comparison (or direct search) methods minimize $\rho$ by systematically searching the $\rho(\beta)$ response surface for the minimum value of $\rho$. These contrasting approaches are illustrated by the Levenberg–Marquardt(68) modification of the Gauss–Newton method (gradient) and the Nelder and Meade(69) simplex algorithm (function comparison). In general, gradient methods converge more quickly than function comparison methods. On the other hand, function comparison methods are easier to encode because they do not involve derivatives or matrix inverses. In the specific case of nonlinear least squares analysis, the derivatives of $\rho$ are well known, therefore many programs are based on the faster convergence of gradient methods such as Levenberg–Marquardt.

In the Levenberg–Marquardt algorithm, the goal is to adjust the parameter values so that the residuals get smaller at each iteration, as shown in Equation (61)

$$\rho^{(k+1)} \beta = \rho^{(k)} \beta + k \mu \nu < \rho^{(k)} \beta$$

where $\rho^{(k+1)} \beta$ is shorthand for $\rho[\beta^{(k+1)} \beta]$ and means the $(k+1)$st (next) iterate of $\rho$. As shown in Equation (62) each new parameter estimate, $\beta^{(k+1)}$, is a combination of the previous iterate, $\beta^k$, and a search vector, $\nu$.

$$\beta^{(k+1)} = \beta^k + \Delta \beta = \beta^k + k \mu \nu$$

where $\Delta$ denotes ‘a change in parameter value’. The keys to the reduction in $\rho$ are the length, $k \mu$, and direction of the search vector, $k \nu$. In the neighborhood of a minimum any function can be expressed as a quadratic. This means that the minimum in $\rho$ can be approximated by its Taylor expansion using the first two derivatives, as shown in Equation (63)

$$\rho^{(k+1)} \beta \equiv \rho^{(k)} \beta + k \mu (\nabla \rho)^T \nu + \frac{1}{2} k \mu^2 \nu^T (\nabla^2 \rho)^T \nu$$

where $\nabla \rho$ is the gradient (first derivative of $\rho$ with respect to the parameters, $\beta$) and $\nabla^2 \rho$ is the Hessian, the matrix of second derivatives with respect to the parameters. As the minimization proceeds, the gradient, $\nabla \rho$, approaches zero. (This is a central feature in Newton-Type methods.) The updated gradient of $\rho$, $\rho^{(k+1)} \nabla \rho$, is given by Equation (64)

$$k+1 \nabla \rho \equiv \nabla \rho + k \mu \nabla^2 \rho \nu$$

Since the form of $\rho$ is known explicitly, the gradient and Hessian can be written in terms of the residuals, $\xi$, and parameters, $\beta$. They are shown in Equations (65–67):

$$\rho = (f - g)^T (f - g) = \sum_i \xi_i$$

$$\nabla \rho \beta = 2 \sum_i \frac{\partial \xi_i}{\partial \beta_j} \xi_i$$

$$\nabla^2 \rho \beta \beta = 2 \sum_i \left( \frac{\partial^2 \xi_i}{\partial \beta_k \partial \beta_j} + \xi_i \frac{\partial \xi_i}{\partial \beta_k} \delta_{kj} \right) = 2J^T J + 2 \xi \cdot H$$

In these expressions, $J$ and $H$ are matrices describing the first and second partial derivatives of the residuals (elements of $\xi$ not $\rho$) with respect to the parameter
vector elements. Substituting these expressions into Equation (64) and setting to zero yields Equation (68)

\[
(k^*J^TJ + k^*H)^k v = -k^*J^T\xi
\]  

(68)

The search direction \( \mathbf{v} \) is determined by solving this system of equations. The Levenberg–Marquardt algorithm solves for \( \mathbf{v} \) by ignoring the second derivatives of the residuals \( \mathbf{H} \) and adding a small diagonal increment \( \mathbf{J}' \mathbf{J} \) to guard \( \mathbf{v} \) from the consequences of strong correlations in the variables. The search direction is given by Equation (69)

\[
k^* v = (k^*J^TJ + k^*\mathbf{H})^{-1}(-k^*J^T\xi)
\]  

(69)

In practice, these equations are not solved by matrix inversion. Gaussian elimination is more reliable and robust. The increment \( k^* \mathbf{H} \) must be large enough to insure that \( \mathbf{v} \) leads to a reduction in \( \rho \). Later in the optimization, \( k^* \mathbf{H} \) must grow smaller at each iteration in order for the algorithm to converge on the optimal parameters. The size of this increment is determined by a linear search. The resulting descent direction is added to the previous parameter estimate, as shown in Equation (70)

\[
k^{+1} = k^* + k^* \mathbf{v}
\]  

(70)

The descent direction moves the estimate toward a zero-valued gradient. This process is repeated until \( J^T\xi \) meets some user-specified tolerance close to zero. The associated parameters simulate the experimental data with minimized residuals. If the parameters model decay data, the model is given by Equation (71)

\[
g = \beta_1 e^{-\beta_1 t} + \beta_2 e^{-\beta_2 t} + \cdots + \xi
\]  

(71)

4.3.2 Global Target Analysis

Nonlinear least-squares algorithms are used in the analysis of a large number of data types, attesting to the power of the method. The difficulty in analyzing complex decays accurately and unambiguously. Global target analysis has evolved from efforts to address this limitation. The central feature of global analysis is the simultaneous analysis of several related experimental responses. The combined responses are analyzed as a group using a single model. The parameter values for each response are not only consistent with that particular response, but with all the responses in the set. In most cases, the confidence intervals around the parameter values are significantly reduced when compared to parameters recovered from the analysis of single responses. Consequently, parameters determined using global analysis have a higher probability of accuracy than their single response counterparts. Nonlinear least-squares fitting is the method of choice in most global analyses, but this method can be implemented using the optimization method of the analyst’s choice. In fact, one of the earliest global analyses used the method of moments to determine the fluorescence lifetime from fluorescence decays.

The reduction in the parameter confidence intervals is a significant advance in itself. The enhanced sensitivity in the ‘goodness of fit’ observed in global analysis has a second important consequence. Physical model evaluation has become an integral part of many global analysis programs. Parameters can fit experimental responses well, yet have no physically meaningful interpretation. In order to avoid physically meaningless parameter values, global target analysis defines the simulated response in terms of physical invariants. Using this approach, a data set should be analyzed using several alternative models. The applicability of the models that were tested is quantified via error (i.e. residual) analysis. As long as the residuals are consistent with the spectrometer measurement error, the data can be associated with a model. It is important to remember that regardless of the goodness of fit, data analysis can only determine that a model is compatible with the data, not prove that a specific process is producing the emission. In general, parameters (pre-exponentials and decay constants) recovered from complex (≥ 3 components) exponential decays are not unique. It is possible to discover a model that fits the data well but does not describe the decay process accurately. Bajzer and Prendergast illustrate this fact by showing that multiexponential intensity decays of some single-tryptophan proteins can be described just as well by considering the tryptophan emission quenched by unspecified energy transfer acceptors ‘present in or close to the protein matrix’ as they are by conformational changes or lifetime distributions.

4.3.3 Maximum Entropy Method

When the decay of fluorophores in locally heterogeneous media are measured, the goal of objective, unambiguous decay analysis is more difficult to achieve. Analyzing such measurements by fitting the data to models selected by the analyst can be risky. If structural nuances are associated with small features in the measured response, those features could be overlooked during fitting to standard distribution functions. The MEM is a powerful method for recovering the value and shape of distributed parameters from dynamic spectral data without a priori assumptions about the nature of the parameters.

A linear matrix transformation models the measurement process, as shown in Equation (72)

\[
\sum_{p} h_{np} \beta_p = g_n - \xi_n \quad \text{or} \quad H\beta = g - \xi
\]  

(72)
where $\beta$ is the parameter distribution, e.g. lifetime distribution (Equation 13), $g$ is the measured response, e.g. donor decay, $\xi$ is the residual vector and $H$ is the transformation matrix relating the parameter to the measurement. Theoretically, the parameter distribution, $\beta$, could be estimated by solving Equation (72) using matrix inversion methods, but this is impractical for several reasons. First, the sizes of the matrices $H$, $\beta$ and $g$ usually prohibit direct solutions. Second, a direct solution would incorporate the influence of the measurement error, $\xi$, into the results. In decay analysis, the transformation, $H$, is an inverse Laplace transformation. The transformation is ill-conditioned which means that small errors in $\xi$ can lead to large errors in the resulting distribution.

A direct solution also defies the nature of the problem. Theoretically, an infinite number of solutions reproduce the measured response within the limits of the measurement error. The MEM solves Equation (72) by minimizing the information content of the parameter estimate, $S(\beta)$, subject to the constraint that the parameter estimate reconstructs the measured data within the limits provided by the measurement error. Equation (73) shows in mathematical notation,

$$S(\hat{\beta}) = -\sum_p \hat{p}_p \log \left( \frac{\hat{p}_p}{\beta_0} \right) - 1$$

subject to $C(\hat{\beta}) = \sum_n \left( \frac{f_n - g_n}{\sigma_n} \right)^2$ (73)

where $S$ is the entropy of the distributed parameter, $\beta_0$ is the integral of the distributed parameter, $\sigma_n$ is the variance associated with measuring the $n$th component of the response and reconstructed data (simulation) vectors, i.e. $f_n$ and $g_n$, respectively. The simulation is given by Equation (74)

$$\hat{f} = H\hat{\beta}$$

(74)

The entropy function measures the information content of the parameter vector. Maximizing $S$, subject to the chi-squared constraint, $C(\beta)$, on the simulation yields the “simplest” distribution, i.e. the one that has the lowest information content (highest entropy), from the family of distributions that represent the data within the fitting criterion.

The MEM algorithm published by Reiter(76) uses constrained nonlinear optimization to solve for $\beta$. The algorithm minimizes the entropy iteratively by solving successive quadratic approximations to the problem. This is similar to the approach used by the Levenberg–Marquardt nonlinear least-squares fittings. The difference here is that the solution at each iteration (step) must satisfy the constraints as well as minimize the objective function. The residuals, which form the constraints, are measured by the chi-squared function rather than sum of squares. The algorithm begins with a quadratic approximation to the entropy function and linear approximation to the chi-squared function in terms of the parameters, $\beta$. Equations (75) and (76) show

$$S(\beta + \Delta \beta) \approx S(\beta) + \Delta \beta^T \nabla S + \frac{1}{2} \Delta \beta^T \nabla^2 S \Delta \beta$$

(75)

$$C(\beta + \Delta \beta) \approx C(\beta) + \Delta \beta^T \nabla C$$

(76)

where $S$ is the entropy function, $\beta + \Delta \beta$ is the updated parameter vector, $\nabla S$ is the entropy gradient (derivative with respect to the parameter elements) and $\nabla^2 S$ is the entropy Hessian. The Hessian is a matrix comprised of the second derivatives of $S$ with respect to $\beta$ on the diagonal and the partial derivatives with respect to $\beta_i$ and $\beta_j$ on the off-diagonals. $C$ and $\nabla C$ represent the value and derivative of the chi-squared function respectively. To minimize $S$ subject to constraints, $C$, we combine $S$ and $C$ via a Lagrange multiplier, $q$. Equations (77) and (78) show

$$L = S - qC$$

(77)

$$L(\beta + \Delta \beta) \approx L(\beta) + \Delta \beta^T \nabla L + \Delta \beta^T \nabla^2 L \Delta \beta$$

(78)

$S$ is maximized and $C$ satisfied when $\partial L/\partial \beta$ and $\partial L/\partial q$, defined in Equations (79) and (80), are zero.

$$\frac{\partial L}{\partial \beta} = \nabla L + \nabla^2 L \Delta \beta = \nabla S - q \nabla C + \nabla^2 L \Delta \beta = 0$$

(79)

$$\frac{\partial L}{\partial q} = C + \Delta \beta^T \nabla C$$

(80)

Combining these two conditions yields a system of simultaneous linear equations, as shown in Equation (81)

$$\begin{bmatrix} \nabla^2 L & -\nabla C \\ -\nabla C^T & 0 \end{bmatrix} \Delta \beta = -\nabla S$$

(81)

The Hessian matrix, $\nabla^2 L$, and gradients, $\nabla C$ and $\nabla S$, can be very large. They can be condensed by re-expressing these quantities in terms of some convenient coordinate axes, e.g. the products of the derivatives and the parameter distribution, so that $\Delta \beta$ can be determined using standard methods for solving simultaneous equations. The parameter vector is updated using the increment shown in Equation (82)

$$\hat{\beta} = \beta + \Delta \beta$$

(82)

In some cases, the increment will be so large, the updated parameter will not be within the region prescribed by the entropy and constraint approximations, i.e. Equations (75) and (76). In such cases, a smaller step replaces the solution of Equation (81). This process is repeated until the convergence criteria are met.
Hypothetically, the entropy and chi-squared gradients are perpendicular at convergence. In practice, this condition may be difficult to achieve. Convergence criteria based on the chi-squared function can produce satisfactory results. The response model for the decay is given by Equation (83)

\[ g = \sum_{p} \beta_p e^{-\lambda_p t} \]  

(83)

where \( \lambda_p \) is the decay rate associated with the \( p \)th element of the parameter distribution, \( \beta_p \).

4.3.4 Multivariate Frequency-Domain Decay Analysis

When the decay of a mixture of fluorophores is governed by first-order kinetics, the emission response to excitation at modulation frequency \( w \) is given by the Fourier transform of the time domain solution (see Equation 15). Specifically, as shown by Equation (84)

\[ z(t) = W_0 e^{-i(wt+\Phi)}W^{-1}z_0 \]  

(84)

where \( W, W^{-1} \) and \( z_0 \) have the same definitions as in the time domain solution. \( \Phi \) is a diagonal matrix of signal amplitudes, \( m_{ii} = m_{ex}/(\omega^2 + \lambda^2_i)^{1/2} \), and \( e^{\Phi} \) is a matrix that has the complex phases of the observed signals on the diagonal. Each element of \( z \) is an oscillation that is demodulated and phase shifted relative to the excitation function. Writing this solution as the Fourier transform of the impulse response we have Equation (85)

\[ z(t) = \tilde{z}(w)e^{iw} \]  

(85)

where \( \tilde{z} \) represents the complex Fourier transform coefficients of \( z(t) \) at frequency \( w \).

The Fourier transform of impulse response also is prominent in the Fourier transform of the kinetic equation. It is the product of the decay transform and the complex frequency adjusted for the initial conditions, as shown in Equation (86)

\[ \frac{d\tilde{z}}{dt} = K\tilde{z} = iw\tilde{z} - z_0 \]  

(86)

This means that at each modulation frequency, the frequency-domain decay coefficients, \( \tilde{z} \), are linear functions of the photokinetics transfer matrix. Sugar(77) showed that when the initial conditions are available, \( K \) could be fit directly to experimental frequency-domain decay data.

When Equation (86) is expanded to multiple modulation frequencies, it becomes a system of linear equations, as shown in Equation (87)

\[ KZ^T = Z^T\Omega - Z_0^T \]  

(87)

where \( Z \) and \( Z_0 \) are matrices constructed from the values of \( \tilde{z} \) and \( z_0 \) measured at all the modulation frequencies (the rows of \( Z_0 \) are identical). \( \Omega \) is a diagonal matrix of complex modulation frequencies, \( \omega_{ij} \) (\( i = 1 : L \)). As long as the number of frequencies, \( L \), is greater than the number of emitting sample components, \( K \) becomes the unknown in an overdetermined system of equations constructed from the complex part of Equation (87). Neal(78) showed that \( K \) is easily calculated from Equation (88) without fitting.

\[ \hat{K} = (Z^T\Omega)_{imag}Z_{imag}^+ \]  

(88)

The initial intensities can be calculated by using \( K \) in a rearrangement of Equation (87), to give Equation (89)

\[ Z_0^T = Z^T\Omega - KZ^T \]  

(89)

4.3.5 Application of Decay Analysis Methods

The global analysis approach is so general that it can be applied with equal facility to dynamic absorbance data, fluorescence lifetime determinations, determination of excited state kinetics and rotational diffusion coefficients. The primary limitations of global analysis are the fact that the analyst must select the photokinetic model to be used in the fit and the limited number of distribution functions that can be used to model the decay.

The MEM has become the standard complement to global/nonlinear least-squares analysis. The MEM recovers a lifetime distribution from fluorescence decays without input from the analyst regarding the number of components or shape of the distribution. In this sense, the method is model independent. It is important to remember that the generalized exponential model embodied by the MEM (Equation 74) does not describe all types of emission decay. For example, fluorophores in polymers and other viscos, anisotropic media emit decays better characterized by stretched exponentials.(79) Decays of fluorophores subjected to excited state reactions are not always amenable to MEM. Decay components can be characterized by negative pre-exponentials (from negative values of \( W \) in Equation 15). The classical MEM program cannot recover distributions that have negative values because the entropy function does not exist in the domain of negative numbers. Newer versions that address this limitation have been described,(80) but are not as widely distributed as the classic version. This limitation also applies to the analysis of anisotropy decays using the MEM. MEM can reveal unusual features in rotational correlation time distributions and improve the ‘goodness of fit’ criteria. The analyst must use some other method to determine if the anisotropy decay components are associated with negative pre-exponentials.

The MFDA method also is model-independent in the sense that the analyst need not select the number of
system parameters to be determined. MFDA results are not subjective because they are calculated from the measured data without reference to simulated data. Here again, it is important to recognize that there are model limitations inherent in the formalism on which the algorithm is based. MFDA treats decay data as if it were produced by first-order processes, whether they were or not. The MFDA formalism also includes the assumption that a pure decay for each component has been isolated prior to the analysis. The results of analysis of pyrene and pyrene excimer fluorescence decay in surfactant micelles by MFDA are illustrated in Figure 20.

The details of measurement protocols such as the signal-to-noise ratio, sampling rate and sampling cut-off can have significant consequences on all decay analysis methods. If the decay is inadequately sampled or acquired with an insufficient signal-to-noise ratio, the accuracy as well as the precision of the analysis may be unacceptable. James and Ware\(^{61}\) have studied the signal-to-noise ratio required to distinguish lifetime distributions from closely spaced discrete lifetimes using time-correlated single photon counting. Shaver and McGown\(^{82,83}\) have studied the impact of measurement conditions on MEM in frequency-domain measurements. Clearly, special attention should be given to the details of the decay acquisition when analysis results are interpreted.\(^{84,85}\) A list of selected decay analysis applications is provided in Table 2.\(^{14,15,22,31,42,86–98}\)

4.4 Matrix Factorization Methods

4.4.1 Self-modeling Curve Resolution

Self-modeling curve resolution (SMCR)\(^{99,100}\) is a numerical procedure for determining the responses of individual components from matrix-formatted data. SMCR resolves...

component responses from bilinear matrices, i.e. matrices that are sums of the outer products of the component responses to experimental variables. For example, the steady-state fluorescence EEM is the sum of the outer products of the excitation and emission spectra of the sample components, so it is an example of a bilinear matrix. The matrix can be written as Equation (90)

\[ M = \sum_{k}^{K} \sum_{k}^{K} \gamma_{k} \mathbf{x}_{k} \mathbf{y}_{k}^{T} = \mathbf{X}\mathbf{Y}^{T} \]  

(90)

where \( K \) is the number of sample components, \( \mathbf{M}_{k} \) is the EEM of the \( k \)-th component and the columns of \( \mathbf{X} \) and \( \mathbf{Y} \) are the component excitation and emission spectra, respectively. Consequently, each column and row of this matrix is a linear combination of the excitation or emission spectra of the sample components.

The columns and rows of every matrix \( \mathbf{M} \) can be expressed as combinations of orthogonal vectors, as shown in Equation (91)

\[ \mathbf{M} = \sum_{k}^{K} \sigma_{k} \mathbf{u}_{k} \mathbf{v}_{k}^{T} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^{T} \]  

(91)

where the columns of the \( N \times P \) matrix \( \mathbf{U} \) are orthonormal (i.e. \( \mathbf{U}\mathbf{U} = \mathbf{I} \), the identity matrix) basis vectors for the column space of \( \mathbf{M} \), the columns of the \( M \times P \) matrix \( \mathbf{V} \) are orthonormal basis vectors for the row space of \( \mathbf{M} \) and \( P \) is the smaller of the two matrix dimensions \( N \) and \( M \). The matrix \( \mathbf{\Sigma} \) is diagonal; the magnitude of each nonzero element, \( \sigma_{k} \), reflects the contribution of the product \( \mathbf{u}_{k} \mathbf{v}_{k}^{T} \) to the variance of \( \mathbf{M} \). The factorization of \( \mathbf{M} \) into orthogonal vectors is called the singular value decomposition. The number of basis vectors is equal to \( P \) (the smaller matrix dimension) rather than \( K \) (the number of fluorophores) because of the superposition of measurement noise on the instrument response. However, only \( K \) of these basis vectors describe variance associated with the spectral signal. The remaining \( P-K \) vectors describe noise and should be eliminated from the matrices \( \mathbf{U} \) and \( \mathbf{V} \) prior to further analysis. When the number of fluorescent components is not known prior to the analysis, \( K \) can be estimated using a number of statistical and signal processing techniques.[101,102] The determination of \( K \) is called rank estimation. This topic is discussed in more detail in section 5.2. From this point, \( \mathbf{U} \) and \( \mathbf{V} \) represent truncated \( N \times K \) and \( M \times K \) matrices, respectively.

The data matrix \( \mathbf{M} \) is the product of \( \mathbf{U} \), \( \mathbf{S} \), and \( \mathbf{V} \), but \( \mathbf{U} \) and \( \mathbf{V} \) are inconsistent with physically meaningful spectral responses. Physically meaningful responses (e.g. spectra and concentrations) must be non-negative. These conditions rarely are met by the columns of \( \mathbf{U} \) and \( \mathbf{V} \). However, since the columns of \( \mathbf{M} \) are combinations of both the columns of \( \mathbf{U} \) and the columns of \( \mathbf{X} \) and \( \mathbf{U} \) and \( \mathbf{X} \) must be linear combinations of each other. Similarly, \( \mathbf{V} \) and \( \mathbf{Y} \) are linear combinations of each other. Consequently, it is possible to reconstruct \( \mathbf{X} \) and \( \mathbf{Y} \) from \( \mathbf{U} \) and \( \mathbf{V} \), respectively. The column vectors \( \mathbf{X} \) are constructed by combining multiples of the columns of \( \mathbf{U} \) so that they form vectors that meet the mathematical conditions on physically realistic responses. The matrix \( \mathbf{Y} \) is similarly reconstructed from \( \mathbf{V} \), but with the additional constraint that the product of \( \mathbf{X} \), \( \mathbf{\Gamma} \) and \( \mathbf{Y} \) continue to equal \( \mathbf{M} \). In many cases, the non-negativity and other constraints do not define unique values for \( \mathbf{X} \) and \( \mathbf{Y} \). Neal et al.[100] described a variant of the original SMCR algorithm which factors \( \mathbf{M} \) into a single solution for \( \mathbf{X} \) and \( \mathbf{Y} \). This factorization of \( \mathbf{M} \) is based on the idea that if the rows and columns are transformed independently, the diagonality of concentration factor matrix, \( \mathbf{\Gamma} \), reflects the quality of the solution. Specifically, Equation (92) shows

\[ \mathbf{M} = \mathbf{U}\mathbf{\Pi}^{-1}\mathbf{\Sigma}\mathbf{\Theta}^{-1}\mathbf{v} = \tilde{\mathbf{X}}\tilde{\mathbf{Y}}^{T} \]  

(92)
where the circumflexes indicate estimated values. The steps of the factorization are:

- Calculate $U$, $\Sigma$ and $V$ from $M$ by singular value decomposition.
- Construct non-negative estimates of $X$ and $Y$ using transformation matrices, $\Pi$ and $\Theta$: $\hat{X} = UP$ and $\hat{Y} = V\theta$.
- Estimate $\Gamma$ from the estimates of $X$ and $Y$: $\hat{\Gamma} = \Pi^{-1}\Sigma\Theta^{-T}$.
- Minimize the off-diagonal elements of $\hat{\Gamma}$.

The values of $\Pi$ and $\Theta$ that diagonalize the concentration factor matrix, $\Gamma$ are determined by constrained minimization of the sum of the squared off-diagonals of $\Gamma$. As this sum is reduced, the $U$ and $V$ are reconciled to the mathematical constraints on spectral responses, transforming them to $\hat{X}$ and $\hat{Y}$. The accuracy of the transformation depends on several factors including the matrix signal-to-noise ratio and the similarity of the component spectral responses that constitute $X$ and $Y$. High signal-to-noise ratio and dissimilar component responses promote accurate transformations.

### 4.4.2 Evolving Factor Analysis

Evolving factor analysis (EFA)\(^{103}\) is a numerical procedure for partitioning matrices when some features of the profile of one of the responses are known. For example, when the eluent from a chromatographic or electrophoretic separation is monitored spectrally, it is known that each system component will have a single maximum in its elution profile. EFA-type algorithms operate on the principle that when the part of the profile associated with a single component is deleted from the matrix the rank of the matrix is reduced by one. In an early EFA algorithm,\(^{103}\) the eigenvalues of sub-matrices constructed by successively adding rows starting from the beginning of the acquisition are compared with eigenvalues of sub-matrices constructed by successively including rows starting from the end of the acquisition. Plots of the eigenvalues were combined to produce crude elution profiles.

Today, more efficient algorithms are used. For example,\(^{104}\) the basic structure for the data collected when separations or kinetics are monitored spectrosopically is given by Equation (93)

$$\Delta = \sum_{k} \xi_k C_k^T = EC^T$$

(93)

where the columns of $E$ represent the absorbance spectra (molar absorptivities times pathlength), and the columns of $C$ represent the time evolution of the sample components, respectively. When the rows associated with the $k$th component are set aside, principal components analysis of the remaining matrix is given by Equation (94)

$$\Delta = Q^*(V^*)^T$$

(94)

The columns of $V^*$ are the singular vectors ($Q = U\Sigma$) of the time profiles of the remaining spectra. Since the time evolution of the $k$th compound is not described by $V^*$, any part of the rows of $A$ that is not described by $V^*$ must be the part of the $k$th component profile. The response of the deleted compound is given by Equation (95)

$$\Delta(I - V^*(V^*)^T) = A_k = \xi_k^C C_k^T$$

(95)

where $\xi_k^C$ represents the part of the $k$th component spectrum that is uncorrelated with the other spectra and $C_k$ is the time profile of the $k$th component. This procedure is repeated for all $K$ components of the sample and the recovered time profiles are used to calculate the spectra of the sample components. Equation (96) shows

$$E = \Delta C^+$$

(96)

where $C^+$ is the pseudoinverse of $C$.

### 4.4.3 Generalized Rank Annihilation Method

The generalized rank annihilation method (GRAM) simultaneously factors two matrices, e.g. sample and calibration matrix, without the potential ambiguity of SMCR or the EFA requirement for unique maxima in the component profiles. The sample and calibration standard matrices, $M$ and $N$, given in Equations (97) and (98), are combinations of the same row and column basis vectors, e.g. fluorescence excitation and emission spectra.

$$M = XL_N Y^T$$

(97)

$$N = X\Gamma_N Y^T$$

(98)

$\Gamma_M$ and $\Gamma_N$ are diagonal concentration factor matrices. Lorber\(^{105}\) realized that the component responses, $X$ and $Y$, could be determined by combining Equations (97) and (98) into a single generalized eigenvalue problem giving Equation (99)

$$M\Lambda = NZ$$

(99)

where $Z = Y^+$ and $\Lambda = \Gamma_N\Gamma_M^{-1}$. The eigenvectors of $N^{-1}M$ are the columns of the pseudoinverse of the matrix of component responses, $Y$. The column response can be calculated directly from $Y^+$ and $\Lambda$, as shown in Equation (100)

$$X = MZA$$

(100)
Figure 21 Resolution of pure excitation (a) and emission (b) spectra of trans-1-(2-naphthyl)-2-phenylethene conformers resolved from mixture spectra by SMCR. Principal component loadings (top) of mixture spectra fall on single lines indicating two components. The principal components (middle) are linear combinations of the component spectra. The spectra (bottom) are reconstructed from combinations of the singular vectors. (Reproduced by permission of the American Chemical Society from Saltiel et al.108.)
The original algorithm has been revised to accommodate rectangular matrices and calibration matrices that do not include all the components in the sample matrix.\(^{(106)}\)

The acquisition need not stop with two matrices. For example, the emission-decay matrix could be acquired as a function of excitation wavelength. The result is a three-way matrix given by Equations (101) and (102)

\[
d_{nmp} = \sum_{k} x_{nk} y_{mk} z_{pk} + e_{nmp} \tag{101}
\]

\[
D = X \otimes Y \otimes Z \tag{102}
\]

The generalized multiplication operator, \(\otimes\), combines three column matrices into the three-way matrix. If the number of sample components that absorb and emit are the same, the spectra and decays of all \(K\) components can be recovered from the three-way matrix. The model embodied in Equation (101) corresponds to a system in which all the components respond independently to all three sets of experimental variables, e.g. excitation wavelength, emission wavelength, and time. Direct trilinear decomposition (DTD),\(^{(107)}\) a variant of GRAM, reduces the \(P\) matrix slices to a single pair and calculates \(X, Y\) and \(Z\) without ambiguity using the approach described above.

### 4.4.4 Application of Matrix Factorization

Spectrometric data matrices are acquired regularly, if not routinely. Multiple wavelength kinetic measurements are used to study dynamic processes in multicomponent systems from photosynthetic reaction centers to polymers. In most cases, these matrices are analyzed using globals or a principal components based variant that fits the decay factors to user specified decay models. SMCR, GRAM and DTD have not been used as widely. GRAM and DTD are projection methods and they are not always robust. On the other hand, GRAM factors matrices without the rotational ambiguity of SMCR. Therefore, it is useful to acquire a second matrix under related conditions when possible. Figure 21 illustrates the trans-1-((2-naphthyl)-2-phenyethene conformer spectra resolved by SMCR of quenched mixture spectra arranged in matrix format.\(^{(108)}\) Moderate measurement errors can cause dramatic oscillations in the results. Alternating trilinear decomposition\(^{(109)}\) is an optimization routine that implements the DTD resolution less stringently and with more stable results. The requirement that the analyst has two samples containing different relative ratios of the same components also may be limiting the use of this method. A second matrix has been generated instrumentally using phase-resolved detection\(^{(110)}\) and using perpendicular emission polarizer settings.\(^{(111)}\) Theoretically, it should also be possible to produce the second matrix by adding a selective quencher to the sample. A short list of matrix factorization applications is provided in Table 3,\(^{(104, 111–126)}\)

5 ERROR ANALYSIS AND RESULT VALIDATION

5.1 Parameter Confidence Intervals

The precision of linear parameters recovered by regression methods can be determined from the variance of the independent variables.\(^{(127)}\) For a linear regression Equation (103) shows

\[
\mathbf{B}_{\text{sample}} = \mathbf{F}^{-1}\mathbf{G}_{\text{sample}} \tag{103}
\]
The variances of the elements on each column of the parameter matrix $B$ are given by the diagonal elements of the following matrix, as shown in Equation (104)

$$ b_i \Psi = \text{var}(F^T g_i) = F^T g_i (F^T g_i)^T = F^T g_i g_i^T (F^T)^T $$  

(104)

In other words, the variance of parameter $b_i$ is $b_i \Psi_{ii}$. It is important to mean center $F$ and $G$, that is subtract the column average from every element on a column, prior to calculating the variance matrices. The off-diagonal elements of $\Psi$, i.e. $\Psi_{ij}$, are the covariances of the parameters which reflect the impact of variation in parameter $i$ on the variance of parameter $j$.

The precision of parameters recovered by nonlinear least-squares also are functions of the variances of the parameters. Rather than mean center $F$ and $G$ to calculate $\Psi$, the variance–covariance matrix of the derivatives of the weighted residuals at the minimum is a convenient estimate of the variance in the parameters. The variance–covariance matrix is given by Equation (105)

$$ J^T \Psi J = (J^T J)^{-1} \quad (105) $$

The square roots of the diagonal elements of $J^T \Psi J$ provide an estimate for the standard error of the parameters. For many applications of nonlinear least-squares these estimates are sufficient, but they are imperfect. They are the variances in the linear approximation of the parameters. (Remember, there is no contribution from the second derivatives in Equation 64.) The estimate also assumes that the parameters are completely uncorrelated, i.e. orthogonal. Unless all the off-diagonals of $\Psi$ are zero, this criterion is not satisfied. Error estimates without these assumptions can be calculated, for example, using Monte Carlo methods, but they are computationally expensive and are generally reserved for exceptional circumstances.

### 5.2 Rank Estimation

The first step in the analysis of matrix-formatted spectral data, that is PCR, PLS, MFDA, SMCR, EFA, GRAM and DTD, is the determination of the number of chromophores or fluorophores that give rise to the observed matrix. Measurement errors superimposed on the fluorescence signal inflate the rank of experimental matrices to the smaller of the matrix dimensions. The singular vectors and singular values are ordered by magnitude, so that the first matrix component, i.e. $u_{1S1} v_{1}^T$, describes the largest fraction of the matrix variance and the last component, $u_{pSpp} v_{p}^T$, describes the smallest. The largest matrix components describe the variance associated with the spectral response, the remaining components describe the measurement error. In the case of high signal-to-noise ratios and moderate spectral overlap, the difference between primary (spectral) and secondary (noise) matrix components is clear in the magnitudes of the singular values. In the case of low signal-to-noise ratios and severely overlapped component spectra, determination of the number of spectral components, i.e. the pseudorank, can be a difficult problem. Determination of the optimal number of matrix factors is critical to accurate analysis. If the number of factors is too low, the model will be inaccurate because responses produced by the sample of interest end up in the residuals. If the number of factors is too high, noise is incorporated into the model, increasing the error of prediction or in the parameters.

There are two types of rank indicators. Some methods compare the variance of the matrix components, i.e. the relative magnitudes of the $\sigma_i$. Other methods compare the frequency content of the singular vectors, capitalizing on the predominance of high frequency signal components in measurement noise. The wisest course is to use the consensus result of several methods. The most rigorous method for determining the number of factors contributing to a model is cross-validation. The optimal number of factors is the number that produces the smallest average prediction error when the matrix is reconstructed using column factors generated by systematically removing the columns of the matrix one at a time. Other variance-based methods include reduced eigenvectors, the indicator function and F-tests. The autocorrelation function (see discussion below) and the Fourier coefficient method estimate the rank by determining the presence of non-random variance (low frequency signals) in the singular vectors.

### 5.3 Residual Analysis

Other measures of fit quality are based on the residuals. The chi-squared function measures the residuals relative to the measurement precision. The reduced chi-squared is given by Equation (106)

$$ \chi^2 = \frac{1}{v} \sum_{i} \frac{(f_i - g(a_i))^2}{\sigma_i} \quad (106) $$

where $v$ is the number of degrees of freedom associated with the residuals, i.e. the number of parameters subtracted from the number of all but one of the measured values. The reduced chi-squared is close to unity when the data have been fitted adequately.

The size of the residuals is not the only indicator of fit quality. The residuals also should distribute randomly around the origin when the measurement error is normally distributed; systematic errors indicate that the data, $F$, are not well modeled by the simulation, $g$. The autocorrelation of the residuals is a simple measure of the presence of structure in the residuals. It is
given by the sum of residual covariances, as shown in Equation (107)

\[ \xi_k = \sum_{i=1}^{N-k} \xi_i \xi_{i+k} \] (107)

The analyst chooses the lag, \( k \). Autocorrelations calculated using \( k \) equal to 1 and 2 are common. Visual inspection of plots of \( \xi_i \) vs \( \xi_{i+k} \) also show indications of trends in residuals. The autocorrelation function can also be used for rank estimation by determining the presence of systematic variance in matrix factors.

5.4 Stability

The stability of a calculation is primarily a product of the algorithm used to perform the calculation. Sometimes, a procedure that is conceptually straightforward inflates computer round-off errors to an unacceptably high level. The best insurance against this is to use software based on well-designed and tested algorithms. The stability of a transformation can be determined from the condition number of the associated matrix.

For Equation (103), the condition number is given by Equation (108)

\[ \text{cond}(F) = \frac{\sigma_{11}}{\sigma_{KK}} \] (108)

where \( \sigma_{KK} \) and \( \sigma_{11} \) are the last and first singular values of \( F \). When the condition number is small, e.g. close to unity, the matrix is well-conditioned. Transformations of well-conditioned matrices are stable and not subject to error inflation. If it is found that a data set is ill-conditioned, the analyst should attempt to use variable settings which will improve the condition number. A complete discussion of this topic is beyond the scope of this article, and can be found in references that discuss multivariate calibration in detail.

6 SOFTWARE

Encoding data analysis algorithms can be time-consuming. Fortunately, programs for most of the methods described in this article are available commercially. The names and distributors of the programs are given in the referenced citation. One alternative to buying the programs is to purchase a programming environment that has basic mathematical and statistical operations encoded already. This will reduce the time and effort to encode these algorithms significantly. Several software packages meet this criterion. They vary substantially in price and function. MATLAB (The MathWorks, Natick, MA) is a general-purpose programming language with graphics that is optimized for matrix computations. Extensive toolboxes that have specialized functions for various applications, e.g. signal processing and image analysis, are available. GRAMS/32 (Galactic Industries, Salem, NH) is a package designed specifically for acquisition and analysis of spectral data. The GRAMS environment includes graphics and many pre-programmed functions to simplify data analysis.

7 FUTURE DEVELOPMENT

As technological advances facilitate the acquisition of spectrometric data, the amount and complexity of spectral data will continue. The trend toward increasing dimensionality also will continue. Some of the impetus behind these trends comes from the interest in resolving the components of complex interactions in situ. The tendency for fluorophore emission to respond to the experimental variables independently leads to the increased selectivity of multichannel measurements. It is clear that many of the measurements described in this work will be acquired with spatial resolution using microscopes. This means that the data analysis methods described here will be combined with and complicated by image analysis and reconstruction.

The data analysis methods, specifically generalized rank annihilation and DTD which recover component responses without unambiguity, will continue to be developed and eventually find wide use. Neural networks have not been widely used to analyze absorbance or fluorescence, but they hold promise as multivariate calibration and pattern recognition devices. In pattern recognition devices, neural networks will be used to identify characteristic signals (fingerprints) in complex data sets. In calibration, neural networks can be expected to compensate for strongly correlated variables and matrix effects and may eventually facilitate calibration transfer across spectrometers.

ACKNOWLEDGMENTS

The author’s sincere thanks go to Brad Rowe and Linda Staib for their excellent and timely assistance in the preparation of this manuscript.

LIST OF SYMBOLS

The following list is not exhaustive, but contains the main quantities discussed in this article.
ELECTRONIC ABSORPTION AND LUMINESCENCE

**Absorbance**

$A, A, A$ log of ratio of transmitted to incident light. Scalar quantity commonly designated by capital $A$.

**Response Parameters**

- $\alpha_f$: fluorescence intensity decay pre-exponential parameter
- $\alpha_c$: fluorescence anisotropy decay pre-exponential parameter
- $\alpha_d$: fluorescence energy transfer decay pre-exponential parameter

**Optical Pathlength**

$b$ distance traveled by light during measurement

**Response Parameters**

- $\beta, \beta, B$: e.g. sample component concentrations
- $c, c, C$: moles of substance per liter of solution
- $\gamma, \gamma, \Gamma$: relative intensity of sample components
- $d$: donor–acceptor distance. Typically represented by $r$

**Dirac Function**

$\delta$: infinitely narrow pulse

**Data Matrix**

$D$: measure of fluorophore rotation. Scalar quantity commonly designated by capital $D$.

**Diffusion Coefficient**

$D$: distance of acceptor from donor at which emissive rate and energy transfer rate are equal. Typically represented by $R_0$. Scalar quantity commonly designated by capital $D$.

**Forster Distance**

$D_F$: distance of acceptor from donor at which emissive rate and energy transfer rate are equal. Typically represented by $R_0$. Scalar quantity commonly designated by capital $D$.

**Excitation Function**

$e$: e.g. laser pulse for time-resolved measurements

**Molar Absorptivity**

$\varepsilon, \varepsilon, E$: nominal absorbance of 1 molar solution through 1 cm pathlength

**Residuals**

$\xi, \xi, \Xi$: difference between experimental data and simulation

**Experimental Variable**

$f, f, F$: e.g. concentration, time

**Intensity**

$I, I, I$: intensity

$I, I, I$: fluorescence intensity

$I, I, I$: parallel polarized intensity

$I, I, I$: perpendicular polarized intensity

$I, I, I$: incident intensity

$I_D$: donor intensity

$I_{DA}$: energy transfer intensity

$I_T$: transmitted intensity

$I_Q$: quenched intensity

$J$: overlap integral

**Generic Instrument Model**

$g$: e.g. fluorescence intensity decay matrix of second derivatives linear transformation matrix

$H$: Hessian matrix

Calculated variables:

- $\phi_\Omega$: quantum yield
- $\psi_\Omega$, $\psi_\Omega$, $\Psi_\Omega$: decay cosine transforms
- $\Theta$: frequency of modulated radiation
- $\delta$: phase lag of emission produced by sinusoidally modulated excitation
- $\sigma$: difference in intensity of fluorescence monitored, through parallel and perpendicular polarizers, scaled by sum of polarized intensities
- $\delta_\Omega$: Real Fourier coefficients of decay
- $\delta_\Omega$: Imaginary Fourier coefficients of decay

**Definitions:**

- **Jacobian matrix**: matrix of first derivatives
- **$k_A$**: rate of photon absorption
- **$k_f$**: rate of fluorescence photon emission
- **$k_{ET}$**: rate of excitation energy transfer from donor to acceptor
- **$k_q$**: bimolecular quenching constant
- **$K_Q$**: generic quenching constant
- **$K$**: photokinetic transfer matrix
- **$L, L$**: Lagrange function
- **$L$**: exponential matrix

APPENDIX I: MATRIX ALGEBRA BASICS

Notation
Matrices are denoted by uppercase, boldface Roman and Greek letters, vectors are denoted by lowercase, boldface Roman and Greek letters. Vectors that are columns of a matrix are denoted using the subscripted, lower case boldface matrix variable, i.e. \( \mathbf{m}_j \) denotes the \( j \)th column of \( \mathbf{M} \). Similarly, vectors that are rows of the matrix \( \mathbf{M} \), are denoted \( \mathbf{m}_i \), where \( i \) represents the \( i \)th row. The matrix element on row \( i \) in column \( j \) is denoted \( m_{ij} \). The variable \( m \) is a generic reference to any single element of \( \mathbf{M} \). Scalar variables that are not drawn from matrices and vectors are denoted by uppercase and lowercase italic Roman and Greek letters. The uppercase boldface Roman and Greek letters, vectors that are rows of \( \mathbf{M} \), and lowercase boldface Roman and Greek letters, vectors that are columns of a matrix are denoted using the subscripted, boldface Roman and Greek letters. Matrices are denoted by uppercase, boldface Roman and Greek letters. Complex variables may be subscripted for identification purposes. For example, \( I_i \) is the fluorescence intensity, where as \( I_0 \) is the intensity of the incident excitation beam. The superscript \( T \) denotes the matrix transpose, \( \mathbf{M}^T \). The superscript \( C \) denotes the pseudoinverse of a matrix, e.g. \( \mathbf{M}^C \). The pseudoinverse is a limited inverse, \( \mathbf{M}^C \mathbf{M} = \mathbf{I} \), that can be used to solve linear systems when a matrix is has no classical inverse. Left superscripts, e.g. \( ^2 \mathbf{m} \), indicate the iteration number in repetitive procedures.

Definitions
1. scalar: single number \( m \)
2. vector: sequence of numbers arranged in a column
   \[
   \mathbf{m} = \begin{pmatrix} m_1 \\ \vdots \\ m_n \end{pmatrix}
   \]
3. matrix: sequence of numbers arranged in a table:
   (a) sequence of vectors
   (b) a linear operator, representation of a linear multivariable function
   \[
   \mathbf{M} = \begin{pmatrix} m_{11} & \cdots & m_{1n} \\ \vdots & \ddots & \vdots \\ m_{m1} & \cdots & m_{mn} \end{pmatrix}
   \]

Special Matrices
1. identity matrix:
   \[
   \mathbf{I} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & 1 \end{pmatrix}
   \]
   \( \mathbf{Ib} = \mathbf{b} \); \( \mathbf{AI} = \mathbf{A} \)

Operations
1. addition:
   \[
   \begin{array}{cccc}
   a_1 & b_1 & a_1 + b_1 & c_1 \\
   a_2 & b_2 & a_2 + b_2 & c_2 \\
   a_3 & b_3 & a_3 + b_3 & c_3 \\
   \end{array}
   \]

2. subtraction:
   \[
   \begin{array}{cccc}
   a_1 & b_1 & a_1 - b_1 & c_1 \\
   : & : & : & : \\
   a_n & b_n & a_n - b_n & c_n \\
   \end{array}
   \]

3. multiplication:
   (a) scalar multiplication:
   \[
   \begin{array}{cccc}
   a_1 & c & ca_1 \\
   a_2 & c & ca_2 \\
   a_3 & c & ca_3 \\
   \end{array}
   \]
   \[
   \begin{array}{cccc}
   a_{11} & c & ca_{11} \\
   a_{12} & c & ca_{12} \\
   a_{21} & c & ca_{21} \\
   a_{22} & c & ca_{22} \\
   \end{array}
   \]

   (b) dot (scalar, inner) product:
   \[
   \begin{pmatrix} a_1 & a_2 & a_3 \end{pmatrix} \begin{pmatrix} b_1 \\ b_2 \\ b_3 \end{pmatrix} = \sum_{k=1}^{3} a_k b_k = \mathbf{a}^\mathbf{T} \mathbf{b}
   \]
   \[
   (1 \times 3)(3 \times 1) \rightarrow 1 \times 1
   \]

2. symmetric matrix:
   \[
   \mathbf{A} = \mathbf{A}^T ; \quad a_{ij} = a_{ji} \quad \text{for all} \quad i, j
   \]

3. inverse matrix:
   \[
   \mathbf{A}^{-1} = \frac{1}{|\mathbf{A}|} \begin{pmatrix} c_{11} & \cdots & c_{1n} \\ \vdots & \ddots & \vdots \\ c_{n1} & \cdots & c_{nn} \end{pmatrix}^T
   \]
   \[
   \mathbf{A}^{-1} \mathbf{A} = \mathbf{AA}^{-1} = \mathbf{I}
   \]
   * square matrices only
   \( c_{ij} \) represents the cofactor of \( a_{ij} \)
   cofactor of \( a_{ij} \) is determinant of \( \mathbf{A} \) after row \( i \) and column \( j \) are deleted

4. pseudoinverse: \( \mathbf{A}^+ = \mathbf{V} \Sigma^{-1} \mathbf{U}^T \) (see singular value decomposition below)
   \[
   \mathbf{A}^+ \mathbf{A} = \mathbf{I}
   \]
if \( a^T b = 0 \), \( a, b \) are orthogonal
\((a^T a)^{1/2} = \|a\|\), vector length

(c) outer product:
\[
\begin{align*}
  a_1 & b_1 \\
  a_2 & b_2 \\
  a_3 & b_3 \\
\end{align*}
\]
\[
= \begin{bmatrix}
  a_1 b_1 \\
  a_2 b_2 \\
  a_3 b_3 \\
\end{bmatrix} = \begin{bmatrix}
  c_{11} \\
  c_{12} \\
  c_{13} \\
\end{bmatrix} = C
\]
(3 \times 1)(1 \times 3) \implies (3 \times 3)

(d) matrix multiplication:
\[
\begin{align*}
  AB &= \begin{bmatrix}
  a_{11} & a_{12} & b_{11} & b_{12} \\
  a_{21} & a_{22} & b_{21} & b_{22} \\
  \end{bmatrix} \\
  &= \begin{bmatrix}
  \frac{2}{k=1} a_{1k} b_{k1} & \frac{2}{k=1} a_{1k} b_{k2} \\
  \frac{2}{k=1} a_{2k} b_{k1} & \frac{2}{k=1} a_{2k} b_{k2} \\
\end{bmatrix} \\
  &= \begin{bmatrix}
  c_{11} & c_{12} \\
  c_{21} & c_{22} \\
\end{bmatrix} = C
\end{align*}
\]

4. Division:
\[
\begin{align*}
  A^{-1} b &= \begin{bmatrix}
  a_{11}^{-1} & \cdots & a_{1n}^{-1} \\
  \vdots & \ddots & \vdots \\
  a_{nn}^{-1} & \cdots & a_{nn}^{-1} \\
\end{bmatrix} \\
  &= \begin{bmatrix}
  c_1 \\
  \vdots \\
  c_n \\
\end{bmatrix} \\
  &= \begin{bmatrix}
  a_{nj}^{-1} b_j \\
  \vdots \\
  a_{nj}^{-1} b_j \\
\end{bmatrix} \\
= \begin{bmatrix}
  c_1 \\
  \vdots \\
  c_n \\
\end{bmatrix} = c
\end{align*}
\]

or \( A^+ b = c \) if \( A \) is not square

5. matrix transpose:
\[
A^T = \begin{bmatrix}
  a_{11} & \cdots & a_{1m} \\
  \vdots & \ddots & \vdots \\
  a_{n1} & \cdots & a_{nm} \\
\end{bmatrix}
\]

6. matrix exponential:
\[
e^A = \begin{bmatrix}
  v_{11} & \cdots & v_{1n} \\
  \vdots & \ddots & \vdots \\
  v_{m1} & \cdots & v_{mn} \\
\end{bmatrix} e^{\lambda_{11}} 0 0 \\
\begin{bmatrix}
  v_{11} & \cdots & v_{1n} \\
  \vdots & \ddots & \vdots \\
  v_{m1} & \cdots & v_{mn} \\
\end{bmatrix} e^{\lambda_{mm}} \\
\times \begin{bmatrix}
  v_{11} & \cdots & v_{1n} \\
  \vdots & \ddots & \vdots \\
  v_{m1} & \cdots & v_{mn} \\
\end{bmatrix} ^{-1}
\]
\[
\text{where } A V = V \Lambda \text{ (see below)}
\]

for diagonal \( A, V = I \)

1 BACKGROUND

Gas chromatography (GC; sometimes called gas–liquid chromatography or GLC) has developed from a single successful application for separating volatile carboxylic acids in the early 1950s into a universally accepted chemical measurement tool spanning the disciplines of chemistry, biochemistry, forensics, toxicology, environmental sciences, and others. The development of GC arose in the context of surging interests in electronics and analytical instrumentation in the post-World War II era. A growing reliance then and now upon physical methods for chemical analyses, such as mass spectrometry (MS) or infrared spectrometry, meant that instrumental characterizations of complex mixtures would be difficult to interpret without prefractionating a sample into individual constituents. GC met this requirement for volatile and semivolatile organic compounds. These compounds constitute only a fraction of all organic substances; however, their relative importance in foodstuffs, cosmetics, and medicines, or in some instances as persistent and toxic pollutants in the environment, guaranteed a role for GC in modern analytical methods.

The speed and effectiveness of GC for separating petroleum materials and natural products such as fragrances were recognized early on and led to a widespread demand for commercial instrumentation. Fundamental developments in descriptions of the chromatographic processes and improved methods of operation provided a foundation for the extension of GC into further applications. This resulted in vigorous activity surrounding GC and the number of abstracts exceeded 1800 per annum after only a decade of development. This pace of publication is comparable to that of today, where about 2000 citations per annum can be seen in results from abstracting services. Careful examination of the literature reveals that much of the essential direction and technology had been described by the early 1960s, although refinements and improvements in the technology have continued. During the 1990s, such advances in the principles of the technique have slowed, although new applications or adaptations of GC abound annually.

2 HISTORICAL REVIEW OF GAS CHROMATOGRAPHY DEVELOPMENTS

In the 1950s the use of stationary liquid phases on solid supports for separating substances within a chemical class rapidly became a generally applicable tool for separating complex mixtures of volatile organic compounds, in contrast to the previous use of an uncoated adsorbent. This was particularly effective in the resolution of constituents in natural fragrances and petroleum samples, and the growth of demand for these separations fostered a nascent industry for the commercialization of GC. Consequently, the availability and convenience of GC instruments for scientists promoted worldwide advances in GC practices and in the description of fundamental principles. Early and nearly complete descriptions of the separation processes were made by the late 1950s, using mathematic models adapted from existing separation methods. Although packed columns were nearly standard items, the advantages of capillary columns were understood and had been tested by 1958.

During the 1960s commercial instrumentation was developed further, assisted by the availability of programmable ovens, an expanded selection of detectors, and other refinements. The four main detectors in use today (flame ionization, electron capture, thermal conductivity, and MS) were described in this period and most detectors were at a comparatively advanced, stable stage of design by the late 1960s. Discussion groups, abstracting services, and journals such as the Journal of Gas Chromatography (later, Journal of Chromatographic Science) and the Journal of Chromatography aided in the dissemination of discoveries. Other resources became available in the Chromatographic Science Series and in compilations from the International Symposium, which were drawn from the Journal of Chromatography. Column technology, which is central to a separation, was advanced with the development of numerous liquid phases and protocols to make possible interlaboratory comparisons of retention.
The fundamentals for separations with packed columns became organized and concise\(^9\) at this time. In short, the essential methods for operating GC instruments, optimizing columns and controlling experimental parameters were developed during the 1960s, even though the technology was rudimentary. The refined technologies of the 1990s, when compared to developments in the 1960s, will be seen as improvements to previously described concepts and principles. Theoretical descriptions were provided with remarkable, though not complete, detail in this decade.

In the 1970s, three main themes arose in GC: the utility for GC methods in the burgeoning environmental and biomedical fields; the growing availability of comparatively inexpensive mass spectrometers as a detector in GC; and the commercial availability of capillary columns. In combination, these three influences radically transformed GC as a measurement science and pushed the method to the state of maturity that is seen today. Capillary columns were known to offer improved resolution over packed columns,\(^{10}\) and capillary columns gradually supplanted packed columns throughout the 1980s. As a consequence, an entire line of investigation, namely, molecular interactions between substances and various stationary phases, and the efforts to create specialized stationary phases, was eliminated. In place of a vast number of stationary phases with specialized tools to evaluate and select an appropriate phase, only a small number of column types with superb resolution now meet most, if not all, analytical needs. Advances in optimization of chromatographic parameters\(^{11}\) in terms of temperatures and flows made high resolution possible and sensible. Moreover, the optimization of column construction with respect to mixed stationary phases (packed columns) or lengths of columns in series (capillary columns) was made possible by the discovery of a linear relationship between partition coefficients and fractional composition.\(^{12}\)

Throughout the 1990s, GC has experienced a period of enormous activity, although fundamental advances have remained relatively stagnant. Any basic advances, when made, occurred in incremental steps. In contrast, data acquisition became facile with inexpensive desktop computers, and comparatively inexpensive GC/MS became commonplace. Whereas in the previous generations, only large institutions could afford GC/MS instruments, the mass-selective detectors and ion traps of the 1990s placed GC/MS within the practical reach of even small laboratories.

3 PRINCIPLES OF GAS CHROMATOGRAPHY

The short summary given below can be supplemented by several extensive descriptions of chromatography, with special attention to GC.\(^{13,14}\) In a GC experiment, a vapor sample is moved with a flowing gas (the mobile phase, generally either nitrogen or helium) through a glass or metal column containing a phase that is immobilized (the stationary phase). The stationary phase is typically a low-vapor-pressure liquid polymer, and is either coated or chemically bonded to a stationary support (either an inert solid or simply the inner wall surface of an open tube, i.e. a capillary column). As the mobile or gas phase is forced, under pressure, through the column, the sample components are also carried toward the detector at a speed dependent upon the chemical structure of the sample components, the characteristics of the stationary phase, the column temperature, and specifics of the column such as gas flow rate and the amount of stationary phase. Differences in the time of passage through the column (the elution time) are described by the extent to which a substance is dissolved into the stationary phase, i.e. the partition coefficient \(K\) which is equal to \([\text{analyte}]_S/[^{\text{analyte}}]_M\), or the ratio of concentrations in the stationary and mobile phases. Thus, the separation process is founded in differences in the partition or solubility of various analytes in the stationary phase. It is the time spent in the stationary phase that prescribes the retention volume: all compounds spend the same amount of time in the mobile phase.

As the molecules are carried through the column by the carrier gas, an increased length of column should permit increased separation between different molecules with different solubilities. Unfortunately, other factors such as diffusion and resistance to mass transport cause broadening of the concentration profiles which lead to losses in resolution. Of all the terms that may be altered, resistance to mass transfer has offered the best opportunity for improvements and improvements have been attained with thin, evenly applied stationary phases; this is best exemplified with capillary columns. In general, control over diffusion is unwieldy in GC because the principal control is found in the selection of the carrier gas, where only two practical selections exist, nitrogen or helium.

Regardless of column design or stationary phase or sample, in GC the critical event is the partition of a substance between the gas phase and the stationary or liquid phase. The partition coefficient \(K\) is proportional to \((P_0)^{-1}\), where \(P_0\) is the vapor pressure of the pure substance. As vapor pressure is proportional to temperature, GC may be considered approximately as a type of distillation method and this general pattern can be seen in the separation of a homologous series of any chemical such as the \(n\)-alkanes. However, the subtle advantage of GC resides in the molecular interactions between the stationary phase and the sample, in which molecular interactions exert distinct influences on the solubility or partition
coefficient. This is expressed in the activity coefficient \( \gamma \) which contains both a thermal (molecular interaction) and an athermal (size) term. Thus, \( K \propto (\gamma P^o)^{-1} \), and resolution is controlled by more than vapor pressure alone; consequently, substances and even isomers within a chemical family can be separated by GC. In this respect, gas–liquid chromatography is complementary to gas–solid chromatography, in which separations occur through surface or adsorption interactions, which afford class separations through the large differences between functional groups or moieties.

A major theme in the development of the principles for GC separation was the creation of liquid phases that offer the best possible activity coefficients for a certain solute or sample. This was deemed necessary owing to the limited resolution of packed columns and led to the creation of a large number of stationary phases with tailored or specific intermolecular interactions. By the late 1970s, over 400 stationary phases were commercially available and confronted practitioners of GC with a problematic choice of the best stationary phase. As noted in the section below on Column Technology in Gas Chromatography, capillary columns afford resolution and separating capabilities that were impossible in previous generations with packed columns. Consequently, some inefficiency in separation could be tolerated if only an approximately good liquid phase was used, and so the number of stationary phases fell to under a dozen during the 1990s.

The discussion above suggests that GC is a fairly mature analytical method that has been well described for nearly two decades. Consequently, progress in fundamentals has slowed and the questions have become refined and focused. This pattern may be seen in biennial reviews which are made through the American Chemical Society focused. This pattern may be seen in biennial reviews which are made through the American Chemical Society entitled Fundamental Reviews, of Analytical Chemistry. (17–19)

4 OVERVIEW OF CONTRIBUTIONS

The discussions in the following articles amplify the themes given above and will reflect the current development of GC as a measurement technology. The reviews have been made broadly readable for those interested in GC, and are current for those who have an interest in recent advances in GC. The general utility of GC for substances that are vital to human health and environmental control is so widespread and effective that it is inconceivable that a dramatically improved technique will arise and suddenly replace GC methods. Certainly, there are no replacements plainly seen among other analytical methods, and GC should be a valued method so long as chemical determinations rely upon physical methods of characterization.

As noted above, one of the key revolutions in GC during the 1990s was the availability and consistency of bonded-phase capillary columns, and these columns have provided unprecedented consistency and resolution in GC methods. The foundations of these advances are described in Column Technology in Gas Chromatography. Another area where advances have occurred in the last decade and where future improvements may be anticipated is data processing. Chemical information can now be gleaned from chromatograms, using advanced methods of pattern recognition or using artificial intelligence to analyze GC findings. The most promising approaches are described along with the essential tools for interpreting chromatograms in Data Reduction in Gas Chromatography. As noted in the introduction, physical methods of chemical characterization were enhanced dramatically with a preseparation method such as GC, and these are described in Hyphenated Gas Chromatography. The performance and precision of GC measurements has been associated with the quality of instrumentation, and these are presented in the contribution entitled Instrumentation of Gas Chromatography. Although the number of liquid phases have been reduced in number, as described above, some knowledge of the chemical and physical properties of liquid phases is advantageous with GC measurements. The contribution entitled Liquid Phases for Gas Chromatography should provide the necessary background with an update on current trends. Perhaps one of the most exciting developments in GC is the addition of separating power through the use of two or more columns with different stationary phases during a single analysis. This approach has undergone a rediscovery for analytical measurements as described in Multidimensional Gas Chromatography. Although early developments in GC were invigorated through the capabilities to resolve and characterize complex mixtures of volatile organic compounds from natural products, useful information can be taken from a GC measurement only with high reliability for sample preparation. This is not trivial for complex, ultratrace or nonvolatile samples. Also, innovative methods of sample handling have extended the use of GC into previously difficult measurements with a wide range of substances. Consequently, any foundational evaluation of GC must include the methods for handling samples, and these are included in Sample Preparation for Gas Chromatography.

These categories include the core areas where GC continues to undergo changes or where recent changes have caused pivotal changes in the method. The sections, it is hoped, will provide a reference both for those who are unfamiliar with GC and for those who wish an evaluation
of the current standards and possible future trends in the method.

Column technology has fostered the development of gas chromatography (GC). As the manufacture of columns, especially capillary columns, has become more reproducible, the instruments have also improved. Chromatographic theory helps to guide the development of both the column and instrument in GC. Aspects of the theory directly related to the construction of columns are summarized. While packed columns can still be made in the local laboratory, the construction of capillary columns has moved to commercial vendors with the introduction of thin-walled fused-silica capillary columns. The technology required for the construction of columns is described.

1 INTRODUCTION

Over the last 40 years, GC has evolved into a widely used technique. Martin first proposed GC in 1951 and used packed columns in his investigations. Almost simultaneously with the commercialization of GC in 1957, Golay purposed capillary columns as a means of separation.\(^1\) By the time of the 1961 conference on GC, Desty reported significant progress in applying capillary columns to petroleum-based samples.\(^1,2,3\) The early investigators were practical and pragmatic, using materials readily available, such as metal tubing for capillary columns and industrial materials for supports.

The invention of fused silica in 1979 was the result of a systematic study of column materials for capillary columns.\(^4\) At about the same time, a group in Stanford’s Electrical Engineering Department reported on the design of a silicon micromachined gas chromatograph, where the gas sampling valve, column, and thermistor were fabricated on a silicon wafer.\(^5\)

The invention of fused silica was significant in several ways. It provided a much improved inertness because of its low metal content, and it influenced stationary phase development because of the smoothness and wetting characteristics of the surface. The roughness of the packings in the packed columns and the metal capillary columns had allowed different phases to be used in column preparation and allowed the individual analyst to prepare columns for his or her own use. Investigators had to develop a better understanding of the interaction between the surface and the polymer used as the stationary phase in order to coat a wide range of stationary phases on to the fused silica. Fused silica also influenced instrument development because it became possible to manufacture very reproducible and stable columns. This article will focus on the manufacture of fused-silica columns and compare the design and manufacturing process with that of packed columns where appropriate.

2 THEORY AND OPERATING PRINCIPLES

The purpose of this article is to discuss GC column technology, not to go into great detail on GC theory. However, theory can be used as a guide for column selection and design, especially for capillary columns. Most commercially available capillary columns are described in terms of coating efficiency, retention index and capacity factor, \(k'_0\), in addition to their physical dimensions [length, internal diameter (ID) and film thickness, \(d_f\)]. Packed columns are described in terms of the support material, its size, and the amount of stationary phase, plus the column dimensions.

The purpose of the GC column is to provide the necessary separation for the compounds of interest. The capacity factor is a relative measure of how much a solute is retained and is defined in Equation (1) as

\[
k' = t_r - t_m
\]

where \(k'\) is the capacity factor, \(t_r\) is the retention time of the solute, and \(t_m\) is the retention time of an unretained peak (the minimum time required for a peak to pass through the column). The capacity factor is related to the partition coefficient (at a particular temperature) by
Equation (2):

$$K_D = \beta k'$$

(2)

where $K_D$ is the partition coefficient of the solute at a given temperature and $\beta$ is the phase ratio of the column, i.e. the ratio of the gas-phase volume to the liquid-phase volume.

Another parameter can be related to the retention time of the solute. The Kováts retention index gives a retention scale relative to a homologous series of compounds, usually the $n$-alkanes. The retention index for a particular isothermal temperature is given by Equation (3):

$$I = 100n \left\{ \frac{\log(t_{rx} - t_m) - \log(t_{rN} - t_m)}{\log(t_{rN} + n) - \log(t_{rN} - t_m)} \right\} + 100N$$

(3)

where $n$ is the number of methylene units in the least retained $n$-alkane and $(N + n)$ is the number of methylene units in the more retained $n$-alkane. Retention indices allow intercomparisons of columns in terms of their relative retention of different classes of compounds. For the siloxane phases, an aromatic compound such as acenaphthylene is used to show the relative differences in the stationary phase retention.

While the separation of components is primarily accomplished by the stationary phase selectivity in packed columns, capillary columns offer greater efficiency. This is considered in column selection along with the stationary phase selectivity. The column efficiency is experimentally determined by measuring the retention time, $t_r$, and the peak of interest’s width at half-height, $w_{1/2}$. The efficiency can then be calculated using Equation (4):

$$n = 5.545 \left( \frac{t_r}{w_{1/2}} \right)^2$$

(4)

This gives the total plates for the column. For capillary columns, the column efficiency is normalized to column length, $L$, and is then given by Equation (5):

$$N = \frac{5.545(t_r/w_{1/2})^2}{L}$$

(5)

and is specified in plates per meter. An additional measure used with capillary columns is the concept of utilization of theoretical plates (%UTE) described by Equation (6):

$$\%UTE = \frac{N}{H_{\text{min}}} \times 100$$

(6)

$H_{\text{min}}$ is the theoretical minimum plate height and is derived from the Van Deemter equation, which is given in short form in Equation (7) as

$$H = A + \frac{B}{u} + Cu$$

(7)

where $A = 2\lambda d_p$, $\lambda$ is a packing factor and is related to the particle shape and uniformity of packing, $d_p$ is the particle diameter, $A = 0$ for capillary columns, $B = 2\gamma D_p/u$, $\gamma$ is a correction term for the packing ($\gamma = 1$ for capillary columns), $u$ is the linear velocity, $D_p$ is the gas diffusion coefficient, and $C = 8(\pi k d_p^2 u)/(1 + k^2 D_p)$, where $k$ is the capacity factor, $d_p$ is the film thickness and $D_p$ is the diffusion coefficient of the solute in the stationary phase. As can be seen from Equation (7), the packed column efficiency is dependent upon the packing diameter, the uniformity of the packing material, and the uniformity of the packing process. The equation is simplified for the capillary column case. For capillary columns, the Golay equations are used.

Golay presented and subsequently published his seminal paper, “Theory of Chromatography in Open and Coated Tubular Columns with Round and Rectangular Cross-sections”, at the International Gas Chromatography Symposium in 1957. In his paper he derived the relationships for both circular and rectangular cross-section columns. For a circular cross-section column with radius $r$, the relationship is given as Equations (8) and (9):

$$du = \frac{2D}{u_0} + \frac{1 + 6k + 11k^2}{24(1 + k)^2} \frac{u_0^2}{dx_1}$$

(8)

$$\frac{du}{dx_1} = \frac{2D}{u_0} + \frac{1 + 6k + 11k^2}{24(1 + k)^2} \frac{u_0^2}{D}$$

(9)

These are now in the form of the Van Deemter equation, given as Equation (7). Note that there is no $A$ term for the Golay equations. The $A$ term deals with the support material in packed columns. For open-tubular columns, the equation is reduced to Equation (10):

$$H = \frac{B}{u} + Cu$$

(10)

The optimum velocity is derived by finding the minimum and is given in Equation (11):

$$\left( \frac{B}{C} \right)^{1/2} = u_{\text{opt}}$$

(11)

Solving the Golay equations for the minimum gives Equation (12) for the height equivalent theoretical plate $H_{\text{min}}$:

$$H_{\text{min}} = \frac{2\tau_0}{1 + k} \left( \frac{1 + 6k + 11k^2}{24} \right)^{1/2}$$

(12)
From these equations, we can see that for the circular cross-section columns the column diameter is a controlling factor for the column efficiency.

Two more concepts are important in the discussion of columns. The first is the concept of resolution, which is a measure of the ability to separate two different solutes, and the second is sample capacity (Equations 13 and 14):

\[
R = \frac{N^{1/2}}{4} \frac{(\alpha - 1)}{\alpha} \frac{k}{(1 + k)} \quad \text{(13)}
\]

\[
R = \text{column efficiency} \times \text{selectivity} \times \text{column capacity} \quad \text{(14)}
\]

Column efficiency is primarily a function of the column diameter for capillary columns and particle diameter for packed columns. The selectivity is a function of the stationary phase and the third term is determined by the eluting compound's interaction between the stationary phase and the mobile phase.

Sample capacity also contributes to the resolving power. Sample capacity influences a column's capability for separation because if peaks are overloaded they will broaden and cause a loss of separation. Pretorius and Smuts\(^6\) derived an equation for sample capacity (Equation 15):

\[
M = \frac{1}{2} \sqrt{H_{\text{min}}} L \pi r^2 (1 + k) C^d_M \quad \text{(15)}
\]

where \(M\) is the weight of sample injected and distributed between the mobile and stationary phases and \(C^d_M\) is the maximum concentration of the component. The concentration of the solute in the stationary phase is dependent upon the nature of the solute and not the geometry of the column. Therefore, any difference in the weight of the sample in the stationary phase should be due to the stationary phase volume, which is dependent upon the geometry of the column. (This argument can also be extended to the mobile phase, where the volume determines the sample capacity.)

The best way to illustrate the effect of geometry on sample capacity is to consider two columns of equal length, coated with the same stationary phase, and with the same phase ratio and therefore the same capacity factor, \(k\). One column has an ID of 0.530 mm and the other column has an ID of 0.100 mm. Using the same stationary phase defines the maximum concentration in the stationary phase and is only dependent upon the choice of the stationary phase. Selecting columns with the same phase ratio also defines the value for the capacity factor and should be the same for the two columns. These assumptions allow the ratio of the expressions for the two different columns to be taken and is shown in Equation (16):

\[
\frac{M_1}{M_2} = \frac{1/2 \sqrt{H_{1\text{min}}} L \pi r_1^2 (1 + k_1) C^d_M}{1/2 \sqrt{H_{2\text{min}}} L \pi r_2^2 (1 + k_2) C^d_M} \quad \text{(16)}
\]

With \(k_1 = k_2\) and the concentration maximum the same, Equation (16) reduces to Equation (17):

\[
\frac{M_1}{M_2} = \frac{\sqrt{H_{1\text{min}}} r_1^5}{\sqrt{H_{2\text{min}}} r_2^5} \quad \text{(17)}
\]

The ratio can be further reduced by substituting from Equation (12) that \(H_{\text{min}}\) is proportional to \(r\). The ratio is reduced to the ratio of the column radius (shown in Equation 18) as an estimate of the effect of the column dimensions on sample capacity:

\[
\frac{M_1}{M_2} = \frac{r_1^{5/2}}{r_2^{5/2}} \quad \text{(18)}
\]

The comparison will become more complex as the lengths, phase ratios, and stationary phases are changed. Table 1 shows the relative sample capacity for different column diameters, but with the limiting assumptions made above. As can be seen from the comparison, as the diameter is decreased the sample capacity is considerably reduced. One development that has circumvented this limitation is to make multiple parallel capillary columns. The sample capacity directly increases as the number of columns increases. The sample capacity decreases at a faster rate than the column efficiency. There are many instances where the sample capacity can be the determining factor in the choice of a column.

The sample capacity of packed columns is higher. A 6 ft \(\times\) 2 mm 5% methylsilicone Chromosorb\(^\circledR\) W 100–120-mesh packed column has about five times the sample capacity of the 30 m \(\times\) 0.530 mm \(\times\) 2.65 \(\mu\)m methylsilicone capillary column. The 6-ft packed column can only generate 3000–5000 total plates whereas the 30-m column can generate 60 000–75 000 total plates when operating near the optimum velocity. This capillary column provides nearly the same sample capacity but improved separation due to column efficiency and better column inertness.

3 COLUMN CONSTRUCTION

3.1 Capillary Columns

The manufacture of capillary columns requires multiple steps. These steps will be briefly outlined to give an overview of the process before discussing the individual steps. To prepare a capillary column requires the choice of the column tubing material and the manufacture of the column tubing, a decision on pretreatments and deactivations, the choice of the stationary phase, the choice of the coating technique and coating solvent, if the stationary phase is to be cross-linked then the choice of the cross-linking initiator, if the column is to be rinsed then the rinse solvent, and the conditioning prior to use.\(^{(7)}\)

A variety of tubing materials have been used for the construction of capillary columns. Initially, commercially available metal tubing was used. This had some inherent advantages for the early investigators in that the surface roughness allowed different stationary phases to be tried and used. The major limitation was the activity of the tubing. This motivated investigators to develop the means for drawing glass capillary tubing. Much of the work used either soda-lime glass (called this because of the Na$_2$O in the glass) or a borosilicate type of glass. The presence of the Na$_2$O lowers the melting temperature of the soda-lime glass, which makes it easy to work with. Similarly, borosilicate glass (which has B$_2$O$_3$ as a flux in the glass) has a lower melting point than SiO$_2$ (see Table 2 for glass composition). Silicon dioxide glass is available as either quartz or fused silica. Quartz is a naturally occurring material obtained through mining and can contain trace metal contaminants, sometimes at significant enough levels to affect the chromatographic performance of the column. Fused silica is a synthetic material prepared by oxidizing tetrahydrochlorosilane to silicon dioxide. This process leads to a very pure material, with very low metal content and a low concentration of chloride. Soda-lime and Pyrex glasses were drawn using a relatively small machine (roughly 20 in by 30 in) that would automatically coil the drawn capillary. This tubing was thick walled and required the ends of the tubing to be straightened. While column end straightening before installation into the gas chromatograph was still the domain of chromatographers in private laboratories and with limited commercialization. Inexpensive drawing machines and devices for straightening the column ends were available to these laboratories.

The purity of the fused-silica material is important because it allows the tubing to be drawn as thin-walled tubing. The primary benefit of the thin-walled tubing is that it is inherently straight. For smaller diameter columns the outside diameter (OD)/ID ratio is increased to stiffen the material. If these columns were drawn with the same OD/ID ratio as the larger diameter columns, such as the 530-mm columns, the tubing would be limp and harder to handle. Thus it is more difficult to maintain the integrity of the sealing surface by requiring smaller diameter ferrules or excessively extruding graphite ferrule material. It is also harder to make the ferrules with the smaller OD columns. Although it is possible to draw other glasses into thin-walled tubing, it is not practical. The presence of the fluxes (Na$_2$O, CaO, etc.) in these glasses considerably reduces the inherent strength of the silicon dioxide. Another mechanism, sodium devitrification, also affects the strength of the silicon dioxide. The presence of sodium eventually causes the glass to form microcracks. With the thicker walled tubing this is not a problem, but the thin-walled fused-silica tubing requires a protective sheath. The protective sheath is necessary because sodium is picked up very easily during the handling of the column. The protective sheath is normally polyimide with a temperature limit in the 350–375 °C range. The temperature limit will be determined by exactly which polyimide is used (above this temperature the polyimide begins to oxidize). The polyimide used at the introduction of fused-silica columns in 1979 could be completely removed by exposure to 400 °C for 1 week. Aluminum has also been used as a sheath material to extend the time of exposure to high temperatures (400–450 °C). When coating the protective sheath on to the thin-walled fused-silica tubing, care must be taken not to trap particles between the polyimide and the fused-silica tubing. Particles can be a source of abrasion and sodium, both of which can cause microcracks and eventually breakage of the column. Therefore, the drawing process now requires a very clean environment and a much larger area. The drawing machine has now become a clean room with enough room for the drawing tower (this requires a ceiling

height of 20–30 ft or higher). The laminar flow for the air greatly reduces the number of particles on the tubing prior to application of the protective sheath. The drawing tower (as shown in Figure 1) consists of the framework for the mounting of the different equipment, the feed mechanism for the preform (typically 1 m or greater in length), the graphite furnace where the preform is drawn down to the required OD and ID, the polyimide applicator, and a length of drying ovens to cure the polyimide before the tubing reaches the take-up reel. If the polyimide is not cured, the drawn tubing will bond together. The cost of preparing the thin-walled fused-silica tubing in private laboratories is essentially prohibitive and fused-silica tubing is therefore commercially prepared almost completely. The preparation of the columns has also shifted to the column vendors.

As the column preparation continues, the next steps will prepare the tubing to be coated with the stationary phase. The coating step can be carried out on untreated material, but many of the stationary phases require pretreatment and/or deactivation steps for efficient columns to be prepared. To illustrate how deactivation affects this process, the coating of a phenylmethylsiloxane of molecular weight 3000 was carried out on Carbowax™-deactivated, D₄-deactivated and undeadivated fused-silica columns. The only column of these three that was an efficient (i.e. well coated) column
was the column with the Carbowax™ deactivation. The phase will bead up on the other two columns. This low-molecular-weight stationary phase is a liquid. To coat the fused silica properly required a higher molecular weight phenylmethylsiloxane (a gum rather than a liquid) to be developed. While these gum phases were readily available for polydimethylsiloxane and 5% phenylmethylsiloxane copolymer at the introduction of fused-silica columns, the other phases were not. Much of the research into capillary columns during the 1980s was devoted to optimizing stationary phase development. Much progress was made in the development of stationary phases with higher molecular weight, hence with better wetting of the column surface. The better wetting of the surface is necessary for the production of efficient columns. These phases now include phenylmethylsiloxane (also denoted 50% phenylmethylsiloxane) and cyanopropylmethylsiloxane, which extend the polarity of columns available to the chromatographer. Simply increasing the molecular weight does not necessarily produce a viable phase. For example, to coat the phenylmethylsiloxane column efficiently on material that has not been deactivated requires a gum phase of molecular weight ~100 000. Grassie et al. reported that with polymers built with the phenylmethyl monomer, the longer the polymer chain length, the more it will react with itself. This manifests itself with a choppy baseline as the column is temperature programmed to 300 °C. Either the polymer chain must be interrupted or a different starting material for the polymer must be used. If diphenyldimethylsiloxane is used as the chain repeating unit, this problem may be avoided.

The gum phases used with fused-silica columns have affected the production of the columns in a different way. With the higher molecular weight stationary phases, the coating solution becomes very viscous as the concentration of the stationary phase increases. This limits the technique of coating the column to primarily the static coating technique. For lower molecular weight phases, the dynamic coating technique can also be used. The dynamic technique will be discussed first. To carry out dynamic coating requires the preparation of a concentrated stationary phase solution (usually in the 10–20% range). A volume of 2–4 mL of this solution is transferred to a coating station consisting of a fitting that includes a connection to an inert purge gas source and a reservoir for the coating solution. A plug of solution is then introduced into the column and pushed along by the gas. The speed at which this plug moves determines the film thickness. This technique will work better with the wider bore capillary columns, such as 530-µm ID columns, because the pressure drop is not as great and therefore the film thickness will not change as much. With longer, smaller diameter columns such as 200-µm ID columns, the film thickness will vary more because the pressure drop is higher. This causes the velocity to increase rapidly as the plug nears the exit of the column. The column to column repeatability is not as good as with the static coating technique.

The static coating technique is carried out by filling the column with the coating solution. Once the column has been filled, the exit end of the column is sealed. The column is then attached to a vacuum source and the solvent is slowly evaporated, leaving the stationary phase behind. Once the column has been evacuated, further reaction and conditioning of the stationary phase can occur in the column. The concentration of the stationary phase can be calculated using Equation (19):

\[
\beta = \frac{\text{volume mobile phase}}{\text{volume stationary phase}} = \frac{V_m}{V_s} = \frac{\text{volume of the volumetric flask}}{\text{density} \times \text{weight of the stationary phase}}
\]

The density for the polydimethylsiloxane phases is 1.0 g mL⁻¹ and the solution phase ratio is easily calculated. For other stationary phases it is necessary to include the density to calculate the film thickness of the stationary phase properly. Thus, to prepare a coating solution of dimethylpolydimethylsiloxane for a phase ratio of 250 would require dissolving 1.000 g of the phase in a 250-mL volumetric flask. Once the phase has dissolved in the solvent, the solution can be used for coating columns.

As seen from the brief description of the static coating process, the choice of the solvent for the stationary phase is important and helps to determine the length of time required to coat the column and the range of film thickness that can be coated with the solvent–stationary phase combination. Solvents with high volatility (low boiling points) such as pentane (36.05 °C), methylene chloride (39.85 °C), and acetone (56.1 °C) have been used for static coating of columns. The polydimethylsiloxane phases are readily soluble in pentane. Whereas the low-molecular weight polyphenylmethylsiloxanes (liquid) are appreciably soluble in pentane, the higher molecular weight gums of the phenylmethylsiloxanes are not and require a different solvent, such as methylene chloride. Since the column length can be between 10 and 150 m, the filled column is a very effective thermometer which responds to small changes in the temperature of the environment around the column while the column is being evacuated. During the evacuation process, the column must be shielded from the temperature swings in the room and, if coating baths are used, from the temperature swings of the heaters. The high-volatility solvents tend to have the higher coefficients of thermal expansion. As the coating solution expands or contracts it will wash the already deposited phase and change the coverage of the column. To a lesser extent, the concentration of the solution changes and will deposit less at higher temperatures or more at lower
temperatures. Sudden cooling of the solution will cause the coating solution to contract and can leave uncoated areas along the column. The thicker the coating solution, the less prone it is to this behavior. If the coating solution is not degassed it may cause cavitation problems when pumped with a high-pressure liquid chromatograph pump. The trapped gas can also cause problems with the evacuation process by expanding and pushing the coating solution along as it expands. This will happen when the pressure drop is high enough to cause the bubble to expand. When this occurs, the whole or part of the column can be washed out. Again, thicker stationary phase solutions tend to reduce this tendency.

The static coating technique requires a high-pressure pump, such as a liquid chromatograph pump, for the higher viscosity solutions to be filled. The columns must then be sealed without trapping air at the end. A vacuum system must be available to evacuate the columns and a means (such as a buffer volume) must be provided to bring up the vacuum slowly. Care must be taken to hold the temperature as constant as possible. Quick temperature swings around the columns should be avoided.

After the columns have been evacuated, the next step in the process is the cross-linking step. The cross-linking agent must have several characteristics to be a good choice for the column-making process:

1. It must dissolve in the coating solution at the required concentration.
2. It cannot be volatile at the column evacuation temperature.
3. It must react at a temperature less than the maximum recommended operating temperature for the phase and preferentially at the lowest temperature as possible (this allows the stationary phase to remain as viscous as possible).
4. It should not degrade or change the stationary phase characteristics. Usually, this is accomplished by the cross-linking occurring at vinyl end caps, methyl groups, or OH groups remaining in the stationary phase or on the fused silica. Cross-linking via the methyl groups on a dimethylpolysiloxane would proceed as follows:

(a) Free radical formation:

\[ R - R \rightarrow 2R^* \]

(b) Abstraction of hydrogen:

\[ R^* + CH_3(SiO)CH_3 \rightarrow RH + ^*CH_2(SiO)CH_3 \]

(c) CH₂ recombination of radicals to cross-link dimethylpolysiloxane:

\[ 2^*CH_2(SiO)CH_3 \rightarrow CH_3(SiO)CH_2-CH_2(SiO) \]

5. The decomposition products should be easily removed with purging and/or solvent rinsing.

The cross-linking is carried out by dissolving an initiator such as dicumyl peroxide (I) in the stationary phase solution. Once the solvent has been evaporated, the column contains the stationary phase and the initiator. The column is then slowly purged with an inert gas as the temperature is increased. Dicumyl peroxide decomposes to the peroxide radical for the cross-linking reaction to occur. After the cross-linking step is completed, the column is usually rinsed and then carefully conditioned under flow. The choice of solvent and thermal conditioning profile will be determined by the stationary phase.

The final step in the process is to test the column. Several different parameters are checked using chromatographically well behaved compounds such as the n-alkanes on the siloxane-based stationary phases:

- the capacity factor, \( k' \)
- the retention index, \( RI \)
- the coating efficiency.

Other compounds are typically chosen to show the inertness level of the column (using acidic and basic compounds) and the resolving power of the column with closely eluting pairs of compounds, such as the xylenes. Application-specific columns are tested with representative compounds for the application.

### 3.2 Packed Columns

The manufacture of packed columns requires fewer steps than capillary columns. These steps will be briefly outlined to give an overview of the process before discussing the individual steps. To prepare a packed column requires the choice of the column tubing material, the choice of the support material, a decision on pretreatments and deactivations of the support material, the choice of the stationary phase, the choice of the coating solvent, and the packing technique.\(^{(10–13)}\)
Several different materials have been used for the tubing material for packed columns, including metal tubing, glass tubing, and polymeric tubing. The choice of tubing will depend upon how the packed column will be used. Glass or glass-lined tubing is used when activity levels need to be reduced. If glass tubing is used, it must be preconfigured to fit the gas chromatograph in which it will be used. The metal and polymeric tubing are also coiled, if necessary. The nature of the packing material may require that the coiling of the metal tubing be done prior to loading of the packing.

The support material is typically a porous material, although glass beads have been used. The materials used for the support include diatomaceous earth, zeolites, porous polymers, and carbon-based material, such as charcoal. For the diatomaceous earth supports, the source of the diatomaceous earth, the treatments, whether acid washed and treated further, and any deactivation steps contribute to the inertness of the column along with the column tubing.

Once the appropriate support material has been selected, the stationary phase is applied to the support by dissolving the phase in an appropriate solvent. Since packed column loadings typically range from 1 to 20% (w/w), the phases tend to have lower molecular weights than comparable phases used with capillary columns. This is because of the limited solubilities of the higher molecular weight gums used for the manufacture of the capillary columns. The stationary phase solution is usually prepared with a higher boiling solvent than would be used with the capillary columns. The stationary phase solution is added to the packing and mechanically mixed, usually by rotating, and the solvent is evaporated.

When the solvent has been removed, the coated support material is then loaded into the tubing using a funnel to direct the material into the tubing and is mechanically agitated, usually by tapping to disperse the material throughout the length of the column. Plugs are placed at the ends of the columns to hold the material in place.

Comparison of the range of stationary phase loading for packed columns with the phase ratios of capillary columns requires the phase ratio of the packed column to be estimated. The phase ratio of a 6 ft × 2 mm 5% polydimethylsiloxane on Chromosorb W®, 110–120 mesh, is estimated to be about 58. The 1–20% range of column loading corresponds to a phase ratio range of 15–300, while the phase ratio range for capillary columns is typically 25–500. To increase the column efficiency, the particle diameter must be reduced, which increases the pressure drop across the column. As with capillary columns, there is a trade-off with increased column efficiency and increased pressure required.

4 PRESENT AND FUTURE DIRECTIONS IN COLUMN TECHNOLOGY

Although fused silica has provided a very stable and inert support, there are applications, such as high-temperature simulated distillation, which will rapidly degrade a methylsiloxane column, both on the inside and outside of the column if the column is polyimide coated. The polyimide has a threshold of ~350 °C for its oxidation. Continuous exposure at 400 °C for a period of about 1 week will strip the column of its protective coating. The methylsiloxane column will also show significant reduction in its ability to partition the solute. These losses have led to other approaches, such as depositing a layer of silica on the interior of the metal capillary tubing and the development of arylene-based stationary phases. The arylene-based stationary phases have arylene units introduced into the polymer backbone.

There has also been a movement towards miniaturization in analytical techniques and instrumentation. Over the past 20 years, researchers have investigated the use of silicon-based materials for capillary columns. This requires the application of microlithographic techniques to column manufacture. One desirable feature of this approach is the fact that the silicon material presents a thin silica layer. This layer is known as the native oxide layer. In the processing of silicon wafers, there are several different methods of growing or depositing an oxide layer on the wafer. The thermal oxidation of the silicon grows the highest density oxide layer. This thermal oxide is much like the drawn fused silica in its density. A second technique for depositing the oxide is chemical vapor deposition (CVD), which can give a more porous silicon dioxide layer. The inherent problem with columns developed using microlithographic techniques is that microlithography is essentially carried out in two-dimensional (planar) space. The channels for the columns are prepared by using controlled etch solutions. The final step in preparing the columns is to seal a second plate over the etched channel and make connections to the plate. Coating these plate columns with stationary phase presents a different set of problems. This approach will require these problems to be solved in order for it to be viable.

Molecular sieves represent another area where some interesting work is being done. UOP mat/sen (El Dorado Hills, CA) has developed several different molecular sieves that are very specific for different gases. While these specialty molecular sieves have applications as traps, there may also be ways to utilize these materials for porous layer open-tubular (PLOT) columns and micropacked columns.

As can be seen, column technology has utilized a wide range of materials and techniques. Further advances will be made through the systematic application of materials.
science, polymer chemistry, and a variety of analytical techniques.

1 Introduction

The data obtained from a gas chromatographic measurement provide the user with details on both the quantitative and the qualitative composition of the sample. This information is displayed in the chromatogram from which information also can be gleaned concerning the performance and quality of the measurement. Quantitative determinations require attention to the relative response of the detector. The assignment of identity of individual constituents is possible in a formal sense only with authentic standards and mass spectra though retention times or indices can be indicators of identity. These aspects of data reduction have been understood for several decades and chemical information can be extracted from a chromatogram with ease and convenience.

In recent years, advanced chemometrics methods have been applied to chromatographic data with intrinsic advantages for probing patterns and trends too subtle or too complex for simple inspection of chromatograms. These methods are rooted in tools such as multivariate analysis and neural network analysis. Such methods are being developed in the area of natural products analysis.

1 INTRODUCTION

A chromatogram is the immediate result obtained from any analytical measurement by gas chromatography (GC) and discloses, for most detectors, all the chemical information about a sample that will be provided by the GC experiment. In addition, details about the overall performance of the chromatograph can be found in the chromatogram and diagnostics are best made when a known sample such as a standard mixture is analyzed. A chromatogram is a plot of detector response (usually in current or voltage) versus time (usually in minutes) following the introduction of a sample into the chromatograph. Most analyses by GC conclude with an understanding of the concentrations or amounts of one or more constituents in a sample and some indication of the chemical identity of such constituents. These results are readily available from the chromatogram and this accounts for the wide acceptance of GC as an analytical tool. At an elementary level, the information and the methods to extract this information have been unchanged during the last several decades and can be found in specific monographs on GC or in general analytical chemistry texts. These will be reviewed and illustrated concisely in the next section.

In addition to the routine use of chromatographic data to answer questions such as ‘is there benzene in my sample and if so how much is there?’, there may be interest in using the chromatogram for comparing with results from other samples. This might be motivated by interests in the origins of the sample or to learn if subtle changes in sample composition had occurred during storage, treatment, or processing of the sample. Normally, human skills of comparison are eclipsed when samples are highly complex or numerous. For example, observing the differences or similarities between chromatograms containing more than 20 peaks can be daunting especially when there may be only minor differences in concentrations of several components. Small differences in chromatograms from GC analysis of volatile organic compounds in blood or urine or breath might be essential in determining an illness, but easily overlooked without computation aids.

While comparisons of complex chromatograms are impractical through manual methods of data reduction, advanced computational methods can provide the necessary tools for such comparisons. These methods have been refined rapidly during the last few years with the wide
availability of affordable, powerful and small computers and the release of specialized, commercial software for advanced data reduction. In the third section below, two of the promising methods for advanced data reduction are described.

2 ESSENTIALS OF CHROMATOGRAPHIC DATA

2.1 General Facets of a Chromatogram

In Figure 1, a gas chromatogram is shown from the analysis of a standard mixture of normal alkanes by gas chromatography/mass spectrometry (GC/MS) and the results are useful for illustrating the information that can be gleaned from an analysis by GC. The important terms for the analyst include the number of constituents (seen ideally as separated or well-resolved peaks) and the relative abundances of each constituent (i.e. the relative heights or areas of each peak, as a rough approximation). Each peak can be defined by a few terms including: the retention time ($t_r$), peak area (or height), peak width ($w$), peak shape distortion or asymmetry factor ($n$), and the retention time for an unretained compound ($t_m$). These all assist in expressing the ultimate goal of a chromatographic experiment, namely, the satisfactory separation or resolution of constituents in a mixture. Other terms such as column length, carrier gas flow rate, inlet pressure, ambient pressure, and column temperature cannot be obtained from the chromatogram and are acquired from independent measurements. Such terms are especially useful when studying the details of chromatographic behavior but are not essential for analytical purposes. All these terms and their meaning have been standardized over the last 30 years$^{1–4}$ and are helpful in determining or documenting the composition of the sample or in exploring separation processes.

The retention time is the timescale of the chromatographic measurement as shown in the $x$-axis of the chromatogram in Figure 1 and is measured from the point of injection (not seen in the figure). Each peak is assigned a retention time measured at the peak maximum for a substance and this is shown in Table 1. For example, the first peak has a retention time ($t_r$) of 8.154 min and the second peak shown has a $t_r$ of 13.084 min and these supply information regarding the chemical identity of that peak as described below. In addition, the peak heights or areas contain information about the amounts of substances in the sample and this too is described below. A salient feature of the chromatogram before detailed discussion is the information so often sought: this sample shows the presence of six constituents and the amounts of each, as a first approximation, appear comparable in order of magnitude.

2.2 Quantitative Aspects of Gas Chromatography Data

The size of any peak is a measure of the amount of that chemical in the sample and there is a proportional relationship between peak area (or peak height) and amount of chemical (number of molecules, moles, mass, or concentration). However, all detectors in GC are operated on principles where there is some discrimination, based upon molecular structure, in the sensitivity of response ($\Delta$ response/$\Delta$ amount). Consequently, any direct comparison of peak heights of various substances without consideration of differences in detector response will be erroneous. Quantitative determinations for GC will be accurate only when the amount or concentration of each analyte is determined using individual calibration curves made for that specific analyte or when relative response factors can be used to normalize a response. Highly selective detectors such as electron capture detector (ECD)

FID, flame ionization detector.

and nitrogen-phosphorus detectors exhibit differences in response factors by orders of magnitude as shown in Table 2.\(^5\) Other detectors such as the FID show a small range of responses within a chemical group such as alkanes though response factors may differ widely between chemical families.\(^6\) In practice, this means that calibration curves should be made for each chemical. Creating individual calibration curves is not burdensome in GC methods since the separation capabilities allow standard solutions to be made as mixtures and calibrations to be made simultaneously for many constituents with a few analyses. The results in Figure 1 were taken from a mass spectrometer detector and the peaks are all alkanes with comparable response factors. Not all peaks have same intensity or height (or area), so differing concentrations between the constituents may be reasonably concluded (Table 1).

If chromatographic performance between samples and standards is identical or very similar, peak heights are suitable for quantitative work or peak areas may be used and are especially helpful when slight variations exist in chromatographic performance. These terms are generated automatically with modern gas chromatographs which are manufactured with data analysis options of varying degrees of sophistication. Difficulties arise in the automated determination of areas for partially resolved components. In the instance when best chromatographic performance is obtained and peaks are still not totally resolved, deconvolution of the chromatogram may be helpful. At present, commercial software packages allow deconvolution of peaks as shown in Figure 2 and these afford refined methods for obtaining peak areas.\(^7\) The additional time and expense in data reduction for these deconvolutions is returned in analytical information that may not be obtainable otherwise.

### 2.3 Qualitative Aspects of Gas Chromatography Data

A second aspect of data reduction is the determination of the chemical identity for a peak and there is no true substitute for a mass spectrum of a peak as shown in Figure 1. The combination of prefractionation by GC with chemical identification by mass spectrometry (MS) explains, in part, the explosive growth of GC/MS instruments and methodologies. This principle about chemical identity cannot be diminished and is especially critical for samples where there is little or no understanding of possible constituents. In some instances where the number of constituents is limited and the sample is drawn from a well-characterized and fairly stable source, retention time of a peak (\(t_r\)) is a de facto measure of chemical identity. In these instances, this measure will suffice as all the proof necessary for an assignment of identity. In other instances, nothing short of a mass spectrum for a peak in a chromatogram and a confirmation of the analyte retention time with an authentic sample will be satisfactory for identifying a constituent in a chromatogram. Regardless, the retention time (\(t_r\)) is and has been an essential term in GC analyses and is best reported as the corrected retention time \(t_0\) where the time is corrected and normalized to the time for an unretained solute (\(t_m\)) as shown in Equation (1). While selection of an unretained solute is more difficult than may be expected, methane is commonly used when column temperatures are high and the detector is a FID (hence the term \(t_m\)). In mass spectrometers, where
Figure 2 The use of deconvolution in obtaining peak areas for a chromatogram (a) in which there is incomplete chromatographic resolution. (b) The individual peaks as seen from deconvolution are shown. The results were generated using PeakFit 4.0.

the filament is usually started after the solvent or air peak has eluted, a reliable determination of \( t_m \) is inconvenient and must be made in a separate determination.

\[
\frac{t'_r}{t_m} = \frac{1}{\beta}
\]

The great facility of a corrected retention time is that there is a direct reference to the partition coefficient \( K \) of the analyte via the phase ratio for the column \( \beta \) as shown also in Equation (2). The value \( K \) is dependent upon stationary phase,

\[
\frac{t'_r}{t_m} = \frac{K}{\beta}
\]

chemical compound, and temperature. So, if stationary phase and temperature are controlled, \( K \) (and thus \( t'_r \)) will be characteristic for a given chemical.

Unfortunately, phase ratios are difficult to obtain or modify so practical chemical measurements require a means to compare results between laboratories. One means used in recent decades to allow comparison of chromatographic results on a given stationary phase is the use of chemical standards to calibrate retention times. A common standard comprised a homologous series of normal hydrocarbons and was called the Kovats index. In this method, the retention of a chemical was expressed in carbon numbers, rather then retention time, by referencing retention for constituents to the retention of a set of \( n \)-alkane standards. Any differences in physical parameters of a column (flow, length, temperature, and phase ratio) would be compensated by this calibration of retention to chemical standards. Such methods were particularly useful since many chromatographers used self-made columns where experimental variables ranged widely. With the advent of commercial capillary columns manufactured with stringent quality control, retention times are matched via software to stored library values.
and adjustments using carrier gas flows are made to meet standard \( t_r \) values. In this way, retention times are directly intercomparable between instruments or laboratory using retention timescales though retention on a column, in a sense, is still being calibrated against a chemical standard.

### 2.4 The Chromatogram as Diagnostic Tool

A final aspect of the chromatogram is that which provides a full measure of the performance of the gas chromatograph including injection port, column, and detector. A full discussion can be seen in sections on trouble shooting\(^1\) and a brief discussion is given here.

Peaks that exhibit tailing are usually an indication of adsorptive interactions between the sample and surfaces in the inlet, column, or detector, poor flow connections, or overloading of the stationary phase. Active sites, that is highly polar or reactant surfaces in the inlet, column, or detector, are usually remedied through chemical deactivation of these sites. Alternatively, improved materials or new columns or improved designs may be needed.

Peaks that show front skewing are indicative of excessive sample loading on the column and the partition coefficient has been pushed into a region where the isotherm of \( C_l \) versus \( C_g \) is nonlinear where \( C_l \) and \( C_g \) are the concentrations of the sample in the liquid and gas phases respectively. This is shown in Figure 3.

When a hydrocarbon sample shows tailing on a fresh, nonpolar or semipolar column, the responsibility is usually poor connections or fitting and is shown in Figure 3. Drifting baselines and more are treated in a recent monograph that experimentalists will find useful.\(^1\)

Band-broadening is a normal part of a chromatogram\(^{10–12}\) and many of the advances in high resolution chromatography have occurred through improved management of band-broadening.\(^13\) Additional band-broadening can arise through the injection of sample and other extra column contributions. These and baseline changes are treated in a series of practical guides.\(^{14–16}\)

### 3 ADVANCED DATA REDUCTION METHODS IN GAS CHROMATOGRAPHY

When chromatograms are simple and information regarding a single (or a few substances) is sought for a measurement, interpretation of the chromatogram can be uncomplicated and rapid. However, when chromatograms contain large numbers of peaks and the patterns defy simple interpretation, advanced methods of data reduction can be useful. There have been two approaches, broadly speaking, to coping with complex samples and these include principal component analysis or cluster analysis and neural network methods. Both methods are computationally intensive and have blossomed with the rise of personal computers in the 1980s and 1990s.

#### 3.1 Multivariate Data Analysis in Gas Chromatography

In multivariate data analysis, data are manipulated so that subtle relationships between constituents in the data can be resolved or clarified. This is done by mathematical methods of recreating the reference points in the information contained in the data and the details of these methods can be found in the articles referenced below. The goal in multivariate analysis is to amplify similarities or differences in data for various samples and generally minimize the number of variables that...
describe a sample. The tools and rules to identify or create the terms for comparisons (principal components in principal component analysis) are beyond the scope of this article. It is sufficient to say that certain peaks or regions of a chromatogram may be compared with other peaks as a measure of similarities. When done for several such comparisons, computational methods allow rapid analysis of results. The end goal is the assignment of a sample as a single data point in two-dimensional (2-D) or three-dimensional (3-D) plots or in multidimensional space. The presence of other measurements in proximity to the sample constitutes evidence of a common or unique composition or identity.

An example of one use of these tools is principal component analysis of chromatographic data from characterizing fatty acids in vegetable oils.\(^{17}\) Though the chromatograms were comparatively simple consisting of only \(~10\) fatty acids, the number of sample types were numerous including olive, coconut, sesame, and others. The results are shown in Figure 4 where the various types of samples are resolved in 2-D and 3-D.

Another example of a chemometric approach to processing gas chromatographic results can be seen in the highly complex patterns from pyrolysis gas chromatograms of polymers.\(^{18}\) Polymers were identified or recognized in poor resolution GC through the presence of functional groups such as olefin, aromatic, amide bonds, carbonyls, and others. Such methods of data analysis may be expected to be beneficial in biomedical and medical applications of GC. One example of a successful application of chemometrics in biochemical measurements was demonstrated for urinary organic acid profiles and uterine cervical cancer.\(^{19}\) In this work, a total of 50 organic acids from urine samples (0.25 mL) were resolved by GC and discriminant (cluster) analysis was performed on the GC data using 16 acids as the variables for discriminating between the two groupings. Discriminant analysis applied to these 16 variables correctly classified 26 urine samples into two separate clusters according to tumor types in the canonical plot.

Advanced data handling of gas chromatographic data has been used in microbiology where the volatile fatty acids in bacteria, long a reliable method to type bacteria through chemotaxonomy,\(^{20}\) were characterized by GC. The data, when treated by chemometrics allowed subgrouping of 169 coagulase-negative staphylococci collected during an outbreak of nosocomial sepsis in a hematologic unit.\(^{21}\) Their findings corroborated the results from conventional typing methods showing

![Figure 4](image-url)

similarities in strain characteristics and, therefore, the same epidemiological origin.

Multivariate analysis methods then, are powerful tools to extract from gas chromatograms details that otherwise elude the unaided eye simply owing to the complexity or subtlety of the data. This is especially so with natural materials such as food odors or vapors. Several more examples are listed in Table 3.\(^{(22–31)}\)

### 3.2 Neural Network Analysis in Gas Chromatography

Another approach to comparing complex chromatograms through what may be nonsubjective computational tools is that of neural network analysis. In all neural networks, the software is used to mimic the human ability to discern patterns. In contrast to humans, computers can operate without fatigue and can survey large amounts of data without the time restraints that humans experience. In neural network methods the network learns to recognize data from known samples. In practice, the chromatogram or the intensity versus retention time pattern of the chromatogram are entered into the input layer after which hidden neuron layers establish weight factors that form a correct answer for the known sample. Other known samples can be trained so that other answers are obtained and an overall weight factor for each neuron in each layer is created, providing that the network properly learns the differences between samples. Thus, unknown samples should be rapidly categorized when chromatographic results for an unknown sample are presented to the trained network. This is especially helpful when the chromatograms are complex and defy reasonable comparisons by humans.

Neural networks have been used in situations where the samples are complex and differences might be due to nonlinear causes. This is especially important in instances where uncertainty exists when two complex mixtures are combined and is illustrated nicely with the recognition of Aroclors in environmental samples.\(^{(32)}\)

In this approach, a simple architecture was developed in which \(\sim10\) peaks were used to classify samples on the basis of the level of Arochlor contamination in environmental samples.\(^{(33)}\)

In another example, neural networks were used to classify vegetable oils after GC analysis of samples for methyl ester derivatives of fatty acids\(^{(34)}\) and to assign botanical origins of vinegar samples.\(^{(34)}\) Polyalcohols, rather than volatile chemicals, were found useful in recognizing the country of origin of various vinegar samples. A similar use of neural networks and GC data from pyrolysis analysis of hashish was found successful in discriminating between hashish obtained from different sources.\(^{(35)}\) Lastly, defects in milk were screened using neural network analysis with GC results.\(^{(36)}\)

Unlike the traditional methods for interpreting chromatograms, these advanced methods can be expected to undergo further refinements in the years ahead. They do, however, establish a basis from which automated data reduction can be successfully completed and used as a powerful tool in the utilization of GC data.

### 4 FUTURE DEVELOPMENTS

The current standards for data processing in chromatographic systems afford a high level of convenience and precision in qualitative and quantitative determinations; these meet or exceed the analytical needs for resolving power of contemporary columns. Nevertheless, the technology is rooted in principles that have been long a part of GC separations and these may be expected to continue well into the future. In contrast, the methods necessary to compare analytical findings for a large number of samples are in nascent stages of application. The methods are developed but not well advanced in daily applications. These chemometric methods may be expected to undergo refinement and general adoption during the next decade. This may be especially so in view of the growing and now major emphasis placed on biomedical chemistry.

Hyphenated gas chromatography (GC) refers to not only the coupling of a GC to information-rich detectors but also the coupling of the gas chromatograph to automated sample preparation techniques. Examples of information-rich detectors include mass and infrared spectrometers, whereas automated sample preparation techniques include solid-phase microextraction (SPME), large-volume injection (LVI), purge and trap (PT), headspace (HS), and gas chromatographic approaches. The gas chromatographic approach involves the wedding of two gas chromatographs and is commonly referred to as multidimensional gas chromatography (MDGC). The union of the automated sample preparation techniques with MDGC and information-rich detectors affords the capability for quantitative and qualitative analysis of a wide variety of sample matrices for analytes at parts per billion (ppb) concentrations. However, not every hyphenated configuration is worth considering, and careful matching of the hyphenated approaches is essential to obtain the maximum analytical benefits.

1 INTRODUCTION

Hyphenated GC has for the most part traditionally referred to the coupling of a powerful separation technique, namely capillary GC, with powerful information-rich detectors such as mass spectrometry (MS) or infrared spectrometry (IR). The term “hyphenation” was first popularized by Hirschfeld in 1980. However, more properly, hyphenated GC should refer to not only the coupling of GC with information-rich detectors but also the coupling of GC to novel automated on-line sample preparation techniques such as PT, static HS, LVI, and SPME. Likewise, the wedding of two gas chromatographs, referred to as MDGC can easily be classified as a hyphenated gas chromatographic technique. In this case, the separation power of at least two gas chromatographs with columns of different separation capabilities is brought to bear. It now becomes readily apparent that the merger of advanced sample preparation techniques with potent information-rich detectors in conjunction with the separation capabilities of capillary GC provides for a powerful analytical approach for the analysis of volatile and semivolatile compounds.
The union, for example, of LVI with MDGC and MS can provide an analytical technique that has detection limits from ppb to parts per trillion (ppt), with typical precision of ±10%. In a similar fashion, the union of MDGC with IR and MS can provide both qualitative (structural) and quantitative (amounts) of target compounds in very complex mixtures such as natural product extracts. The union of SPME with GC and MS can afford the capability for the analysis of ppb levels of target compounds in environmental samples. The underlying theory to hyphenated GC, that is the union of GC with information-rich detectors and automated on-line sample preparation techniques, rests with the fact that the information gained from the data generated by a GC hyphenated approach possesses the potential to be several orders of magnitude more powerful and useful than that obtained from employment of the techniques separately. This does not mean that every hyphenated technique is worth using or even considering. For example, coupling a GC fitted with a column having inadequate separation capabilities with an MS defeats the purpose of the technology. Thus, adequate thought as to the distinct advantages of each component of the marriage must be carefully considered before confirming the union. In other words, thoughtful and careful matching of hyphenated approaches is essential to the realization of the desired benefits.

The combinations possible using only a few mergers of GC separation with on-line sample preparation and detectors are almost endless, particularly when additional separation techniques such as liquid chromatography (LC), supercritical fluid chromatography (SFC), and capillary electrophoresis (CE), as well as additional detectors such as inductively coupled plasma mass spectrometry (ICP/MS), are coupled to a GC. For the purposes of this account, the sample preparation techniques (i.e. pre-GC) discussed are SPME, static HS, PT, LVI, and MDGC. The information-rich detectors (i.e. post-GC) discussed are MS (unit mass and high resolution) and IR (vapor phase (VP) and matrix isolation (MI)).

2 PRE-GAS CHROMATOGRAPH AUTOMATED ON-LINE SAMPLE PREPARATION TECHNIQUES

Sample-enrichment techniques in chromatographic analyses are generally employed because the concentration of the analyte of interest is below the detection limit of the analytical instrument. In some other cases the analyte must be removed from its matrix because introduction of the sample matrix would not be compatible with the desired chromatographic technique. In either case, the analyte must be accumulated in some fashion. This is usually accomplished by transferring the analytes from the parent matrix into or onto another matrix having a well-defined character which is compatible with the chromatographic procedure.

2.1 Solid-phase Microextraction

The information presented for SPME theory and practice is a concise summary of a comprehensive treatise of the topic covered by Pawliszyn. SPME is fundamentally a solvent-free sample preparation/enrichment technique having qualitative and quantitative potential. A relatively thin film extracting phase of very small volume, \( \leq 1 \mu\text{L} \), is firmly coated and bound to a fused silica fiber which in turn can be exposed to a sample matrix. The sample matrix can be room air or aqueous solutions and in some limited cases organic solvents. The extracting phase bound to the fiber is, in a large number of cases, very similar to the phases employed in capillary GC technology. Polar or nonpolar phases such as poly(dimethyldisiloxane) (PDMS) and carbowax/divinylbenzene (CWDVB) and combinations of each can be employed.

The most convenient configuration of SPME technology is depicted in Figure 1. The thin fragile fiber is housed when not in use inside a tube-like structure, which is reminiscent of a GC syringe needle. Exposure of the fiber to the sample matrix of interest is effected by gently sliding the fiber outside of the housing and into the matrix. This exposure can be performed manually or automatically and both devices are available from Supelco, Inc. (Belleville, PA, USA). The partition coefficient of the analyte of interest between the sample matrix and the fiber coating material governs the amount of analyte extracted by the fiber coating. Obviously then, an analyte equilibrium can eventually be established between the sample matrix and the fiber. This behavior renders the SPME approach ideal for quantitative analysis. Furthermore, the presence of a very small amount of coating, which in turn removes very small amounts of analyte, is not likely to alter the sample matrix to any significant extent. SPME can also be used in qualitative analyses by employing a variety of coatings varying in polarity.

From a quantitative perspective, the mass of analyte extracted by the coating is linked to the equilibrium of the analyte in a three-phase system defined by the sample matrix (such as water or air), the fiber coating, and the HS of the sample (Figure 1). Assuming control of the volume of the fiber and its coating, the HS, and the sample matrix, placement of the fiber is not critical. Thus, extracts of the HS above a sample of interest or extracts of the matrix itself can be obtained.
Consequently, direct contact of an SPME fiber with a well-defined sample configuration can lead to quantitative results.

Several extraction parameters have been documented as having meaningful impacts on qualitative and quantitative aspects of the amount of analyte extracted by the fiber. These include fiber conditioning, fiber type, exposure time and location (liquid or HS), temperature, salting (sample ionic strength), pH, and agitation.\(^{2-6}\)

There are, thus, some practical steps that can be taken to optimize each of these parameters to the benefit of the desired end result. To a first approximation, selection of the fiber type can be governed by the age-old adage that “like dissolves like”. For example, if polar analytes such as flavor compounds are of interest, then a polar material such as CWDVB would be a logical first choice. A combination of temperature with exposure location can be used to an advantage. For example, sampling of the HS above a particularly complex matrix at increased temperature could possibly reduce the complexity of the materials extracted by the fiber. Adjustment of the pH of an aqueous sample can alter the nature of the species in solution and thus alter the extraction performance of the fiber. Adjustment of the ionic strength of an aqueous sample with the addition of simple ions from salts such as NaCl can bring about the salting-out phenomenon, thereby improving the performance of the fiber towards the analyte of interest. Agitation of the sample through sample stirring in liquid cases improves the performance of the SPME fiber; likewise, use of fiber vibration also improves the performance of the fibers, particularly as it relates to required sampling times. It should be mentioned here that control of the sampling time is very critical in obtaining reproducible results. Autosamplers can control sampling times to the second, thus excellent precision can be obtained even though equilibrium has not yet been reached.

The successful implementation of SPME technology rests in large part on a properly conditioned SPME fiber. Failure to properly condition an SPME fiber can result in unacceptable accuracy and precision. Fortunately, proper conditioning parameters have been well established for all of the commercially available SPME fibers, and these should be followed to the letter to ensure acceptable performance of the fibers. During use, fibers should be periodically examined closely, usually employing a microscope to ensure that no loss in phase coating has occurred through use.

\(\text{Figure 1} \quad \text{Description of an SPME extraction device.}\)
2.2 Solid-phase Microextraction/Gas Chromatography

Having now established basic theories surrounding SPME, there are some operating principles associated with effective coupling of SPME to GC that must be addressed. Most SPME applications have been developed for GC, with a few applications for high-performance liquid chromatography (HPLC). The successful interfacing of SPME to GC, to produce the hyphenated technique SPME/GC, rests with the theory that analytes captured on the nonvolatile thin film can be efficiently thermally desorbed in a reproducible fashion. This process can be viewed as the reverse of extraction from a sample matrix. To accomplish desorption effectively and reproducibly, a high carrier gas linear velocity coupled with an increased temperature must be consistently established. Furthermore, the time for desorption must be carefully controlled even though theory would indicate that desorption times of seconds at 200 °C should be sufficient for most volatile or semivolatile analytes.\(^{(2)}\)

Standard GC injection ports, such as split/splitless, can be effectively applied to the reproducible thermal desorption of analytes from an SPME fiber. One slight modification of the inert injection port liner is required to ensure the necessary linear velocity around the fiber. In general this involves changing the standard split/splitless liner of 3–5 mm internal diameter (i.d.), for a liner having an i.d. of approximately 0.8 mm and operating the injection port in the splitless mode. This small change results in an injection port volume change in approximately 3 s for the 0.8 mm liner compared with 44 s for the 3 mm liner. Such a dramatic change positively influences the desorption process, resulting in analytes being effectively transferred to the GC column in a narrow band. Additional ways to produce analytes in a narrow band include using a capillary GC column with a thick film stationary phase or cryofocusing the analytes at the front of the GC column using subambient GC oven temperatures. Rapid injection of the needle and simultaneous exposure of the fiber also facilitate the concentration of analytes in a narrow band. The formation of a focused narrow band of analytes directly effects the performance of the separation, either maintaining or reducing the maximum resolution of the GC column.

2.3 Automated Solid-phase Microextraction/Gas Chromatography Application

The enantiomeric distributions of volatile components in essential oils can be accurately and precisely determined using automated SPME/GC.\(^{(2,7)}\) Employing a PDMS SPME fiber of 7 μm film thickness, a GC fitted with a column capable of separating optical isomers and an MS as detector, the optical isomer distributions in a grapefruit and a lavender essential oil were determined (Figure 2). The approach was relatively simple, involving automated sampling of the HS above the essential oil samples contained within a sealed 1.8 mL sample vial. The results obtained from the SPME approach were very precise having an average percentage relative standard deviation (RSD) of less than 6. The results were also accurate, agreeing very well with earlier findings using a heartcutting GC approach. The accurate and precise results were obtained without establishing equilibrium conditions, because such essential sampling parameters as fiber exposure time, sample HS volume, fiber desorption temperature, and sample temperature were carefully controlled. Likewise, evaluations of selected fiber types were conducted until the nonpolar fiber PDMS was found to yield reproducible results.

2.4 Headspace/Gas Chromatography

HS analyses using GC can be subdivided into three general categories.\(^{(8–12)}\)

1. The sample for chromatographic analysis is obtained from a closed vessel where the material under investigation is caused to come into equilibrium with its vapor at a specified temperature. Once equilibrium is established the concentration of the analyte does not change with time if the temperature is held constant. When a sample is taken from the “static HS” of an isothermally sealed vessel the equilibrium is altered. Thus, the procedures associated with taking a sample must be reproducible.

2. The sample for chromatographic analysis is obtained from a gas stream which has been purged through the sample matrix, usually water. The purge gas, now
laden with the analytes, is usually passed through a trap which is inert to the purge gas but capable of efficiently capturing the analytes. Once trapped, the analytes are usually thermally desorbed onto the GC column. This PT approach is limited by some extent to the capacity of the trapping matrix, thus breakthrough volumes must be carefully established.

3. The sample for chromatographic analysis is obtained from a gas stream that has been passed over the sample matrix, such as soil or over the top of a water sample. As expected, the gas stream in this case is much less efficient when compared to the approach described in category 2 above.

### 2.5 Static Headspace/Gas Chromatography

Static (equilibrium) HS analysis is based on the theory that an equilibrium between a condensed phase and a gaseous phase can be reproducibly established for the analytes of interest and that the gaseous phase containing the analytes can be sampled reproducibly. Naturally, this approach will not be very successful when the analytes of interest possess very low vapor pressures because very little of the analyte will be found in the gaseous phase. Elevated temperatures, changes in pH, and the presence of additional electrolytes can in certain cases be employed to increase the analyte vapor pressures.

When coupling the static HS sample-enrichment approach to a GC, several key details and parameters must be carefully attended to. The combined instrumentation usually consists of two individual units, the static HS unit and the GC with appropriate detector. The two units are connected via a thermally controlled inert transfer line that serves as a source of carrier gas for the GC as well as a mode for the transfer of the analytes from the static HS unit to the GC column. In some cases, the two units are also linked and synchronized for automated sample preparation and analysis by software programs available from the manufacturers. Flow control and purity of the carrier gas are essential. Flow is normally controlled in the HS unit employing flow control valves. As the basic premise of static HS experiments rests with the presence of a thermally stable sealed environment, providing a leak-free thermally stable instrument configuration is fundamental to the successful operation of the system. All commercially available static HS systems have detailed descriptions of processes necessary to ensure a leak-free environment. Accurate and durable thermocouples are also provided.

The operation of the instrumentation usually follows the following sequence of events. Appropriate carrier gas flows and temperature zones are established. Additional carrier gas flow is initiated to sweep the lines, sample loop, and needle. A sample in a sealed vial is allowed to equilibrate at an elevated temperature for a specified length of time (Figure 3). The sealed sample vial is raised onto a needle that punctures a septum and pressurization gas fills the vial to a predetermined level. The vial is allowed to equilibrate for a relatively short time to ensure complete diffusion of the pressurization gas with the sealed sample vial’s atmosphere. A vent valve is opened and the pressurized contents of the sealed sample vial exit the system through a thermally controlled sample loop of previously selected volume, usually ≥ 1 mL. The vent valve is then closed and the contents of the loop allowed to equilibrate for a specified time. Next a multiple port valve is activated, placing the sample loop in the carrier gas stream. The carrier gas then sweeps the contents of the loop through the heated transfer line and into the GC. Usually upon initiation of sample transfer to the GC, instrumentation software is employed to automatically begin the chromatographic separation and data collection. Automated multiple sampling configurations can be employed that will perform repetitive analysis of multiple vials, essentially repeating the steps outlined above.

From the description of the operation and sequence of events outlined above for the static HS/GC experiment, an appreciation of the number of possible variables can be obtained. Thus, successive samples undergoing incremental changes in a number of static HS parameters could be used to optimized the analytical procedure. The parameters that are manipulated in order to optimize the procedure include times, temperatures, and pressures associated with sample heating, sample equilibration, loop fill, loop equilibration, and sample transfer. In some cases, manufacturers will provide software that allows for automated systematic changes in these and other key parameters, leading to an optimized approach.

### 2.6 Dynamic Headspace (Purge and Trap)/Gas Chromatography

The fundamental underlying tenet governing dynamic HS (i.e. PT) analysis, is that the change in the mass of a volatile or semivolatile analyte with time can be expressed in terms of the volumetric flow rate of a stripping inert gas. That is, it is physically possible to strip volatile and semivolatile compounds from solid or liquid matrices by passing an inert gas over or through them and that the amount of material stripped can be related to the amount of gas passed through the matrices. Coupling this physical behavior with the capacity to trap the stripped materials on an inert trapping media affords an excellent opportunity for sample enrichment. Several important assumptions underlie the acceptable performance of PT:

- the concentration of the analyte in the stripping gas is equilibrated with the concentration in the condensed phase;
The liquid or solid matrix is essentially nonvolatile;
the distribution constant of the analyte is not
dependent on the analyte concentration.

The issues associated with coupling a PT unit to a GC
are very similar to those described above for the coupling
of a static HS unit to a GC. The two units are connected
via a thermally controlled inert transfer line that can serve
as a source of carrier gas for the GC as well as a mode of
transfer for the analytes from the PT unit to the GC. Most
often the PT and GC units are linked and synchronized for
automated sample preparation and analysis. A leak-free
environment is critical with PT as well as thermal stability.

The manipulation of the instrumentation follows the
general sequence of events described below. Carrier
gas flow compatible with the GC is established and
temperature zones are equilibrated. In PT techniques,
the system is not sealed as in the static approach, thus
the HS above the sample need not come to equilibrium.
Instead, the sample is placed into a chamber, at a pre-
selected temperature, that is sparged with carrier gas at
a specified rate and time (Figure 4). The sparging may
take place by allowing the carrier gas to pass through a
liquid or solid or over the HS above the liquid or solid.
The sweeping carrier gas removes the analytes from the
matrix and transports them under a thermally controlled

Figure 3 A typical sequence of events in static HS analysis. (Reproduced courtesy of Tekmar Instrument Company.)
environment to a trap. The trap is usually allowed to come close to room temperature prior to transfer of the analytes. After a specified time has elapsed the sparging is stopped. It is important to note here that the characteristics of the solid sorbent material contained within the trap can vary over a wide range. The amount and type of trapping material is usually preselected, based on the types of analytes under consideration. Once the analytes have been stripped from the matrix to the trap, a multiple port valve is activated and the trap is heated and backflushed, thereby desorbing the analytes from the sorbent material and transferring the analytes to the GC through the heated transfer line. The GC column can be cryocooled below ambient temperatures to facilitate the capturing of the analytes in a narrow band at the head of the GC column. Once the transfer of the analytes to the GC is complete, computer software programs can be employed to begin the GC analysis. During the chromatographic separation process the temperature of the trapping material is normally raised to a value slightly higher than the desorption value. This increase in temperature cleans the sorbent material of residual material and renders the trap ready for the next sample.

To optimize the analytical procedure for target analytes, most instrumentation is equipped with the capacity to systematically increment the salient PT parameters.
The parameters that may be manipulated in order to optimize the procedure include: sample purge time, carrier gas purge flow rate, and sample temperature. Although not under the control of the instrumentation, a number of other parameters have significant impacts on the PT experiment. Among these are the sample size and the choice of the trapping media. In general, increasing the amount of material to be sparged will increase the amount of analyte captured on the trap. There are some practical limits to this approach, most of which are dependent on the character of the sample matrix. For example, too much solid material could possibly retard the efficient flow of stripping gas. Likewise, increasing the amount of a liquid sample that possesses some foaming characteristics may result in contamination of the system with undesirable sample matrix components. The most popular adsorbent for the enrichment of trace volatiles and semivolatiles from different matrices is Tenax® GC. Tenax® GC is an organic polymeric material, poly(2,6-diphenyl- Shirring phenylene oxide). The retention of unsaturated and polar material on the Tenax® GC is such that the material has found wide applications in environmental analyses, flavor analyses, biological fluids, and human volatiles. The thermal stability of Tenax® GC at temperatures of approximately 350 °C coupled with its low affinity for water further substantiate it as a very acceptable and usually the preferred trapping medium for analysis of volatile and semivolatile organic compounds by PT techniques.

Thus, by way of comparison, dynamic HS techniques/gas chromatographic techniques afford powerful applications in the areas of the qualitative and quantitative analyses of trace levels of volatile and semivolatile materials. Conversely, static HS/GC techniques afford powerful applications in the areas of qualitative and quantitative analyses of minor volatile and semivolatile components.

### 2.7 Applications of Static and Dynamic Headspace Gas Chromatography

The chemical composition of essential oils has been shown to be related to a variety of factors including age, genotype, and geographical growing locations. In an application of static and dynamic (i.e. PT) HS techniques, quantitative and qualitative differences in the distribution of components in an essential oil were documented (Table 1). Through the use of an information-rich detector, MS coupled to the GC, qualitative information on two sources of coriander oil was obtained. Quantitative percentage distribution values for the components of the two were gathered using a flame ionization detector (FID) coupled to a GC. Both the static and dynamic HS approaches were successful in detecting statistically significant differences in the two coriander oils. In addition, both approaches agreed on the major components of each oil, as well as the relative distribution of each component. The precision of the static HS approach was found to be slightly better than that of the dynamic approach. The use of the MS and FID detectors allowed for the determination of sample 1 as an aged sample due to the presence of increased amounts of the linalool oxide, known to increase in aged essential oil samples.

#### 2.8 Large-volume Injection/Gas Chromatography

The injection system of a gas chromatographic system is designed to introduce accurately and reproducibly a small representative amount of the sample being investigated into the column without degrading the maximum separation efficiency of the column. The most common injection techniques are split, splitless, and cold on-column. Split injection is normally employed for minor component analysis where the solute concentration in the sample is present at concentrations greater than 50 ppm (50 ng µL⁻¹). The splitless injection technique, if properly implemented, is most frequently used for trace component analysis in the range from 0.1 ppm to 200 ppm. Cold on-column injection allows the sample to be deposited directly onto the front of the column and has an applicable concentration range similar to the splitless technique. The major advantages of the cold on-column technique are twofold. First, the sample is not subjected to the high temperatures required for split and splitless injections that could cause analyte decomposition or artifact formation. Second, as an intermediate flash vaporization step is not present, discrimination of higher-boiling components is minimized.

limitation of these three most common injection techniques is that the sample volume is limited to less than 2 µL. Vogt et al.\(^\text{17}\) developed another technique, programmed temperature sample introduction (PTV) that overcomes the 2 µL constraint and allows a larger aliquot of the sample analytes to be deposited onto the column while simultaneously eliminating the solvent. This injection technique is now more commonly referred to as LVI.

Figure 5 is a diagram of a PTV inlet. The PTV inlet closely resembles the classical split/splitless inlet as the sample is deposited in a liner. The carrier gas enters the liner at the top and exits at the bottom, and a solenoid valve allows for switching between split and splitless operation. A functional difference between the PTV inlet and a split/splitless inlet lies in the temperature control. Conventional split/splitless inlets normally operate at elevated temperatures (>200 °C) where the sample is flash vaporized before entering the column. Although the PTV inlet can operate under these elevated isothermal temperatures, it is also capable of rapidly heating or cooling the liner. Heating rates in excess of 10 °C s\(^{-1}\) and subambient cooling are common. Operationally, the sample is injected onto the inlet liner, usually at a temperature below the boiling point of the solvent. The inlet is then rapidly heated to transfer the sample from the liner to the front of the column in a very narrow band, thus preserving the separating power of the column. The capability of introducing the sample into the inlet at lower temperatures affords numerous advantages and are similar to those described for the on-column inlet.

The most important feature of the PTV is the capability for ultratrace analysis (i.e. sample concentrations below 1 ppt) via the introduction of sample aliquots up to 1 mL. This is accomplished by operating the PTV in the solvent venting mode. The preferred implementation of this is referred to as SVSF. The chromatographic events are divided into five time zones and are described below.

1. **Pre-injection** The split valve is open, GC and inlet temperatures are at initial values and the column head pressure is at normal operating pressure.

2. **Sample injection** Immediately before the sample injection the column head pressure is reduced to ambient (stop flow). The sample is injected onto the inlet liner at a slow constant rate defined by the solvent boiling point, solute vapor pressures, inlet temperature, and gas flow rates. Injection speeds of 50 µL min\(^{-1}\) are not uncommon, resulting in 10 min to inject 500 µL. During this time the inlet conditions are such that the solvent vaporizes and is swept from the inlet liner. Solute molecules, possessing lower vapor pressures (higher boiling points), remain in the liner as a liquid or solid.

3. **Post-injection** The syringe needle is withdrawn from the inlet and the run-time clock starts (time zero). The inlet conditions of stop flow remain in effect, allowing further purging of the remaining solvent.

4. **Sample transfer** The column head pressure is restored to normal operating pressure and the split valve is in the splitless mode. The solutes are transferred onto the column by rapidly heating the inlet liner.

5. **Sample analysis** The GC temperature program starts and, after appropriate times, the inlet returns to the split mode and then starts its cool down to the initial temperature.

A prerequisite for proper quantitative analysis via LVI/GC requires the vapor pressures of the solutes being analyzed to be significantly higher than that of the solvent. Failure to meet these conditions will result in a nonreproducible loss of solute and poor precision. Optimizing the injection speed relative to temperature, flow rates, and vapor pressures cannot be underestimated if precise quantitation is required. Also, a constant slow injection at a definable rate requires the addition of a computer-controlled injector. These injectors are commercially available.

### 2.9 Applications of Large-volume Injection/Gas Chromatography

GC is routinely used for the analysis of many environmentally significant assays.\(^{17,18}\) The determination of trace components in water usually includes sample preparation steps that enrich the analytes and remove the matrix. The sample enrichment is frequently a time-consuming and labor intensive operation. Elimination of the sample enrichment process would not only decrease analysis
GAS CHROMATOGRAPHY

10
costs and increase sample throughput (via automation), but would also increase the precision of the method. LVI successfully addresses these concerns by both directly injecting the water without preconcentration and by incorporating an in-vial extraction of the water into an organic solvent. Other categories, such as the analysis of beverages, have found significant assay improvements using LVI techniques.

2.10 Multidimensional Gas Chromatography

High-resolution GC incorporating capillary columns is capable of separating and quantifying hundreds of compounds in a single run and has been used for the analysis of complex mixtures such as natural products, biological fluids, and environmental samples since the early 1960s. Depending upon the analytes of interest, even the optimum GC system cannot resolve all of the components in a simple mixture of less than 10 compounds. In addition, as GC detectors such as FID and MS have improved by decreasing detection limits, analysts have come to realize that almost every peak in a GC chromatogram of a complex mixture is most probably a combination of more than one component. MDGC was developed to address this situation. In its simplest form MDGC is defined as a GC system of two or more columns of different selectivity and a device that enables the selective transfer of a portion of a chromatographic run from one column to the second column (a process known as heartcutting). The incorporation of columns of different selectivity is imperative as columns of identical selectivity (stationary phase) would add little value toward increased resolution of analytes. In addition, the hardware used to effect the transfer should be inert with respect to the analytes of interest so as to maintain the maximum efficiency of the separating columns.

Numerous different hardware implementations of capillary-to-capillary heartcutting MDGC systems are commercially available. Most are based on pneumatic flow control first introduced by Deans in 1968. A comparison of three different implementations of MDGC was presented by Gordon et al. A diagram of one of these systems in a dual-oven configuration is shown in Figure 6. The operation of a typical MDGC system for heartcutting includes three basic operations:

1. An initial separation is performed on the first column (i.e. precolumn), without transfer of eluent to the second, or analytical, column.
2. The retention time windows (the run time immediately before to the time immediately after) for the analytes of interest are determined from retention times obtained from the precolumn separation. The sample is injected a second time onto the precolumn and, at the appropriate times, the solutes are heartcut to the analytical column.
3. Final separation occurs on the column under temperature program conditions.

Precise balancing of the pressures and volumetric flows of the MDGC system is paramount. Key components essential to the proper functioning of an MDGC system are a fixed restrictor and a midpoint restrictor. The fixed restrictor is normally a short length of narrow-bore (100–150 µm) uncoated deactivated fused silica column. The combined pressure drop of the fixed restrictor and the mid-point restrictor should be equal to that of the analytical column at normal operating conditions of

![Figure 6](image)
temperature and flow. Failure to balance the pressures in this fashion will result in changes in the retention times on the precolumn during heartcutting, when compared to the initial separation performed without heartcutting, resulting in either incomplete transfer of the analytes of interest or transferring more of the precolumn eluent than desired. A cold trap situated in front of the analytical column serves to trap the heartcut material eluting from the precolumn as a relatively broad band into a sharp band, thus preserving the resolving power of the analytical column. Evaporating carbon dioxide or liquid nitrogen under pressure can be used as cryogenic materials.

As mentioned earlier, the selectivity of the two columns in the MDGC system should differ. For example, if a polar column such as polyethylene glycol is used as the pre-column, then a dimethylpolysiloxane-based analytical column is usually a good choice for the analytical column. Such differences in separation fundamentals multiply the effectiveness of the MDGC separation.

Computer control of the valve sequences necessary to perform an MDGC analysis is required for reproducibility. If the heartcut starts to early, other analytes could be transferred to the analytical column and potentially co-elute with the compounds of interest and, conversely, if the heartcut is initiated late, the compounds of interest may not be transferred to the analytical column. Precise control of numerous hardware operations is required to obtain reproducible results. These include:

- the timing of the heartcut valve;
- turning on and off the cold trap;
- the exact flow rate and opening and closing of the mid-point split valve;
- the start of the temperature programming of the analytical column oven.

2.11 Applications of Multidimensional Gas Chromatography

Most successful MDGC applications address many issues associated with both sample preparation and analysis. Among the issues are:

- target compound analysis;
- use of precolumn to essentially replace classical fractionation of the sample;
- decreases in sample loss and artifact formation due to classical sample fractionation;
- total sample analysis via sequential heartcutting.

The application of MDGC techniques to target compound analyses in complex mixtures employs and addresses many of the issues listed above. For example, MDGC techniques were applied to the analysis of a target compound in rice and to tobacco smoke. The compound 2-acetyl-1-pyrroline has been determined in a crude complex rice extract. Sample preparation involved preparing a methylene chloride extract of the rice followed by injection of the crude extract into an MDGC system. Thus, no classical fractionation was required, eliminating any loss or artifact formation. Furthermore, total extract analysis by sequential heartcutting was available but not necessary for this application. Tobacco and tobacco smoke, like most complex mixtures, are known to contain hundreds of semivolatile components. A conventional single-column capillary gas chromatogram of a tobacco smoke sample is shown in the top of Figure 7. The bottom of this figure shows an expanded section of the full chromatogram. The section from approximately 52.5 min to 53.5 min appears to contain 2–4 peaks and mass spectral scans were able to identify an ethyl-substituted pyrazine as well as numerous unidentifiable...
components. This same region of the separation was subsequently heartcut to a second capillary column resulting in the chromatogram shown in Figure 8. Mass spectral scans were able to confirm the presence of nine identifiable components.

3 POST-GAS CHROMATOGRAPH SAMPLE ANALYSIS TECHNIQUES

The underlying principle governing sample detection and analysis by GC is governed by well-defined consistent responses of a particular sensor (i.e. a detector) to the presence of an analyte within the detector’s environment. In GC, the presence of the analyte within the detector’s environment is accomplished by the appropriate interfacing of the end of the GC column with the sensor of choice. Each detector will present its own set of requirements for successful interfacing to a GC.

The output of the detector is called a response, and there is a wide array of relationships between the characteristics of a detector and the characteristics of analytes. Generally, the amount of analyte within the zone of the detector governs the amount of the detector response. However, the chemistry of the analyte including, for example, its structure and stability, dramatically affects the ability of the detector to register a response.

In order of importance in a chromatographic system, the detector ranks a very close second behind the GC column. Scott has listed seven major detector specifications that are important: detector linearity, linear dynamic range, detector noise level, detector sensitivity, pressure sensitivity, flow sensitivity, and temperature sensitivity.

Detectors are not universal linear devices. That is, detectors provide a linear response to changes in concentration over a definable range. This linear response usually takes the form of a linear plot of concentration on the x axis versus detector output on the y axis. In some cases the detectors for gas chromographs can provide a linear response over a concentration range of more than two orders of magnitude. Once this linear range has been defined for the analyte of interest, then the linear dynamic range of the detector has been established for that analyte.

Detectors have a net response, that is, random changes in signal levels, even in the absence of an analyte. This random response is termed detector noise. Minimization of detector noise is critical to the performance of any system. When detector noise is minimized, detector sensitivity is improved. Detector sensitivity is defined as the minimum concentration of analyte that can be discerned from the random noise. Thus, if the noise is consistently low, sensitivity can be maximized. The degree of detector sensitivity to changes or fluctuations in pressure, flow, and temperature vary greatly depending on the detector. For mass spectrometers all three of these variables have a significant impact on detector performance. For FID, provided that the temperature is high enough to prevent analyte condensation, temperature changes are not as significant to detector performance.

A diverse array of detectors are now currently being used in GC applications. In a number of cases these detectors can be described as information rich. That is, not only do these detectors provide evidence for the presence of an analyte, but they also furnish structural information concerning the analyte. The two most popular detection systems fulfilling the requirements as information rich are MS and IR. The following sections will discuss the theory and instrumentation surrounding these two systems.

3.1 Gas Chromatography/Mass Spectrometry

Many of the basic principles governing the performance of a GC/MS system are those associated with gas flow and vacuum parameters. The GC must operate over a wide range of gas flows and pressures whereas the MS must operate under reduced pressures. Calculations surrounding the optimization of these parameters associated with each component of the GC/MS system can be made; however, approximations provide for adequate values and detailed calculations are not required. Assuming that the mean free path of ions (i.e. the molecular flow) within the MS is sufficient and that the vacuum pumping speed is adequate to handle the incoming gas flow from the GC, then the successful wedding of GC with MS will be possible. There is a very practical reason for maintaining molecular flow. When molecular flow is established, molecule–molecule and ion–molecule reactions and interactions are virtually eliminated. A vacuum
in the range of $1 \times 10^{-5}$ torr is normally required for most MS experiments. These types of reactions are undesirable in the GC/MS experiment because they have the potential for the production of additional molecules and ions that will complicate the molecular fragmentation patterns of the resulting data. Such complications will severely hinder the ability to interpret the resulting mass spectra.

Although not basic to the performance of a GC/MS system, the computer is a necessary component with which to realize the full potential of the GC/MS system. Thus, when speaking of current commercially available GC/MS systems, it is assumed that the actual system consists of a GC, an MS, and a computer (Figure 9). In most current configurations, the computer controls both the GC and the MS. Furthermore, the data collected from a GC/MS experiment is stored and can be evaluated employing software programs commonly available on most commercial systems.

The GC/MS interface provides an acceptable means by which the GC carrier gas with accompanying analytes eluting from the end of the GC column may enter the MS ion chamber under vacuum. When capillary columns are employed, the flow rate through the column is most often less than 3 mL min$^{-1}$. Thus, with current vacuum technologies all of the GC capillary column flow can enter the MS ion chamber with no sacrifice in the vacuum requirements. This capability is very advantageous in that all of the analyte present in the GC column can find its way into the MS ion chamber, thereby affording the potential for maximum sensitivity.

Two types of GC/MS interfaces, both with advantages and disadvantages, dominate those currently employed: direct and open split. With the direct interface, all of the analyte exiting the GC column enters the MS, thereby improving maximization sensitivity. From a practical hardware aspect, however, use of the direct interface requires that the GC/MS be vented should changes in columns be required. Venting of the MS requires exposure of the MS ion chamber to the room atmosphere. To prevent significant damage to the components in the ion chamber, which are very sensitive to air and water at elevated temperatures, this venting must be controlled and done only at room temperature. Failure to follow these procedures can drastically reduce the lifetime of many of the MS components to unacceptable values.

When open-split interfaces are used, changing a GC column does not require venting of the MS. In the open split configuration ample make-up carrier gas is supplied to the MS, thereby excluding the entry of air and water. Conversely, with the open-split interface, not all of the analyte exiting the GC column enters the MS ion chamber. This results in reduced sensitivity. Depending on the application this reduction in sensitivity may not present an issue for the desired analyte. Thus, use of a direct or open-split interface for GC/MS experiments should be evaluated on a case-by-case basis.

One of the fundamentally critical aspects of optimum performance of a GC/MS system rests with the proper installation of the GC column in the MS. Having properly conditioned the GC capillary column and established the desired carrier gas linear velocity, insertion of the end of the column directly into the MS ion chamber is possible. Very close attention must be paid to the proper insertion depth into the MS chamber. Manufacturers of GC/MS systems are very clear on the necessity of performing this step accurately. Improper installation of the GC column can lead to a complete absence of instrument performance.

To establish the necessary vacuum within the MS ion chamber receiving the carrier gas flow from the GC will often require the presence of two vacuum pumps.
A roughing pump and an ion chamber pump (usually a turbo or diffusion pump) comprise the dual pumps. Continuous monitoring the vacuum in a GC/MS system is important in assessing proper functions. With a properly installed capillary GC column having the dimensions 30 m long, 0.25 mm i.d., 0.25 µm film thickness, and a linear velocity of approximately 30 cm s⁻¹, the pressure in the MS ion chamber is approximately $5 \times 10^{-5}$ mm Hg. This vacuum reading is adequate for proper functioning of most commercial systems. When installing a GC column in the GC/MS system, 12–24 h are normally required to achieve equilibrated thermal and pressure parameters.

After having established stable operating temperatures and pressures, mass spectrometers must be properly calibrated. Conveniently, GC/MS–computer manufacturers provide user-friendly software controlled procedures for calibrating the MS. Many quadrupole mass spectrometers are calibrated using perfluorotributylamine (PFTBA). Under computer control the MS is autotuned to target parameters associated with the mass spectrum of PFTBA. Manual tuning of the MS is possible, but it is very time-consuming. The computer output from consecutive autotunes can be used to diagnose the performance and status of the GC/MS system. For example, systematic increases in the amount of multiplier voltage can indicate that the ion filaments are deteriorating. The presence of ions at $m/z = 18$ (water), 28 (nitrogen), 32 (oxygen), and 40 (argon) strongly indicates a leak in the system. The strong indication of a leak requires immediate attention or the GC/MS system performance will dramatically and rapidly deteriorate.

In the normal course of events, venting or shutting down of the GC/MS system will become necessary. Proper attention to manufacturer recommendations for shutting down the MS will prevent abnormal deterioration of the system. Depending on the type of ion-chamber pump employed, decreases of temperature or spinning speed will be required as part of the venting process. When and only when these requirements have been met is it safe to open the MS to the atmosphere and conduct the necessary repairs or changes. Should repairs extend for a period of time, it is important to protect the MS from exposure to dust and moisture. Once repairs or changes have been made then the MS may be pumped down and operations resume.

From a data acquisition perspective the GC/MS–computer system set-up affords many diverse options. In particular, the type of mass-spectral data gathered can be controlled through instrumentation settings. For example, the initial set-up for the analysis of an unknown mixture would most probably involve collection of the mass spectral data in the scan mode. Data collection in this manner provides a total ion chromatogram consisting of a plot of total ion response as a function of time. Data gathered in this way has qualitative implications. The response can be related to the number of ions present, this in turn having quantitative implications. In a second mode of data collection, data from only selected ions may be collected, yielding a selected ion chromatogram (SIM) consisting of a plot of the selected ion response as a function of time. This approach also has quantitative aspects.

From a qualitative perspective, a GC/MS–computer system represents a very powerful physical probe into the structure of analytes. Using the normal, essentially standard, instrumental system configuration settings for gathering total ion chromatograms in the scan mode affords the potential for searching mass spectral databases having more than 100,000 mass spectra gathered under the same standard conditions. Thus, should the GC separation provide for good resolution of the components of interest, automated searching of mass spectral databases (libraries) can furnish valuable data concerning the structure of the analyte. The mass spectra are generated through the fragmentation of the analyte under a well-defined set of conditions yielding ions. These ions usually have a charge of −1, thus the obtained plot of ion abundance versus mass to charge ratio, $m/z$, can be viewed as the mass spectrum of the component. The search can readily be accomplished by automatically submitting, via instrumental software programs, the mass spectrum of the unknown analyte for comparison against the mass spectra contained in the database. Most automated search routines will provide a match quality ranging from 0 to 100, with 100 being a perfect mass-spectral match. The instrumentation can also provide a graphical representation of the mass spectrum of the unknown analyte alongside that of the library spectrum. Very close examination of the output from the library search routines is mandatory to ensure accurate structural assignments. At this point, combination of the separation parameters from the GC with the results from the MS represents a very powerful analytical combination. That is, a combined assessment of both the analyte retention time and the analyte mass spectrum gives more confidence in the structural assignments. In addition, as the amount of ions present can be related to the amount of analyte present, quantitative analysis by total ion current (TIC) can also be realized.

Should quantitative analysis of a known component be the main thrust of the GC/MS experiment, then the instrumentation can be configured in the SIM mode. In this mode, only ions associated with the analyte of interest will be collected by the MS–computer system. This approach provides for increases in specificity and sensitivity. The specificity is improved because only ions associated with the analyte of interest are collected. For
the same reason, the sensitivity is increased because only a few ions, i.e. two or three, are being collected versus approximately 300–500 being collected in the TIC mode. Both internal standard and external standard calibration methods are possible with GC/MS instrumentation. Thus, GC/MS–computer instrumentation set to collect data in the TIC mode has powerful qualitative implications, whereas instrumental settings in the SIM mode have powerful quantitative implications.

All of the issues associated with applications associated with GC/MS are also valid when analyses are pursued with GC/high-resolution MS. Low-resolution instruments have been defined arbitrarily as those instruments that separate unit masses up to m/z = 2000. An instrument that can resolve two ions differing in mass by at least one part in 10–15 × 10^3 is generally considered a high-resolution mass spectrometer. For example, a mass spectrometer that can resolve an ion mass of 600.00 from one of mass 599.95 would have a resolution of 10,000. With this mass resolution capability the data from high-resolution mass spectrometers can be used to calculate the ion atomic composition. The possibility for high mass resolution is realized by the introduction of an electrostatic field after or before a magnetic field along the path of the ions. Ions are generated in the source and they are accelerated toward the analyzer. As the ions enter the magnetic field they are directionally focused. Upon entering the electric sector, which is perpendicular to the flow of the ions, the ions are again curved. This application of double focusing is the fundamental theory supporting the resolution capability of high-resolution MS.

3.2 Applications of Gas Chromatography/Mass Spectrometry

GC/MS currently finds a very wide array of applications including analyses of biological tissue, petroleum residues, pesticides, essential oils, and pharmaceuticals. In one specific case, analysis for and speciation of street drugs has been accomplished using a GC/MS approach. Following derivatization with pentafluoropropionic anhydride (PFPA), GC separation with MS detection of isomers of the street drug MBDB was accomplished in 9 min. Interpretation of the MS spectral data assisted in determining the structures of the isomer. In some cases GC/high-resolution MS is employed to provide accurate mass confirmation of the presence of drugs of abuse.

Polychlorinated biphenyls (PCBs) are widespread toxic organopollutants. A method for qualitative and quantitative analysis using GC/MS for PCBs in soil has been developed. Advantage of the properties of MS is taken through the use of a 13C-substituted PCB as an internal standard. The presence of the 13C label in the PCB did not significantly affect the retention time of the PCB. Furthermore, the presence of the 13C atoms in the PCB produced a unique mass spectrum having ions attributable to the heavier 13C. These unique ions allowed for quantitation of the PCB levels in selected soil samples.

3.3 Gas Chromatography/Fourier Transform Infrared Spectroscopy

Two distinct analytical approaches that can be classified as gas chromatography/Fourier transform infrared spectroscopy (GC/FTIR) have dominated the recent literature. The techniques and instrumentation requirements for each approach are so significantly distinct as to require separate descriptions of the fundamental theory and hardware governing the successful application of each approach. In this light, the two GC/FTIR approaches are considered in independent sections.

3.4 Gas Chromatography/Fourier Transform Vapor Phase Infrared Spectroscopy

The fundamental theory underpinning the successful functioning of gas chromatography/Fourier transform vapor phase infrared spectroscopy (GC/FTVPIR) systems relies in large part on the ability to rapidly acquire multiple entire IR spectra in a very short time, i.e. four spectra per second. This is possible because modern spectrometers employ a rapid scanning Michelson interferometer for measuring the IR spectrum. The rapid acquisition of spectral data is also a fundamental requirement because very low levels of components, nanograms, will pass through the IR beam in a few seconds with properly functioning capillary GC.

Following collection of the spectral data, Fourier transform mathematics converts the time-domain data, an interferogram, into frequency-domain data, an IR spectrum. This calculation is accomplished using a computer, due to the significant amount of data required to adequately represent the IR spectrum. Gram–Schmidt mathematics can also be performed on the spectral data to yield a total response chromatogram (TRC). A TRC is a plot of IR response versus time that is very similar in presentation to the plots obtained from MS response versus time, a TIC.

A simplified diagram of a GC/FTIR system can be found in Figure 10. The light from the IR source passes through the interferometer and then through a flow cell, i.e. a light pipe. Any light that passes through the flow cell is focused on a detector where the light is converted into an electrical signal. The electronic signal is ultimately converted, via computer-driven mathematics, into an IR spectrum. One end of the light pipe is inserted into the end of a capillary GC column. Thus, three operations are
occurring, simultaneously: IR light is continually passing through the light pipe, effluents from the GC column are entering and exiting the light pipe, and the detector is collecting the IR spectral data. At selected times only GC carrier gas is present in the light pipe, essentially when no analyte is exiting the GC column. Under these conditions an IR spectrum is taken which serves as a blank spectrum. A blank spectrum is essential for the mathematical calculations involved in the conversion of the interferogram to the IR spectrum.

From a hardware perspective, GC/FTVPIR has some unique requirements. A constant inert and dry purge gas, such as nitrogen, must continuously purge the optical system. Among the reasons for this obligation are:

- Exclusion of air, particularly carbon dioxide, from the optical path is essential due to its intense IR adsorption around 2250 cm$^{-1}$.
- Exclusion of water is essential because of its intense IR adsorption around 3500 and 1600 cm$^{-1}$, as well as water’s ability to degrade the IR transmission properties of the KBr windows attached to the ends of the light pipe. Water will react with the KBr windows, resulting in the windows acquiring a frosted look, which severely hinders the transmission of IR light.
- Dry air will result in premature oxidation of the IR source.

The temperature of the optical path must be kept constant, ≥200°C. Variations in temperature cause changes in sensitivity and changes in flow rates, not to mention subtle variations in the characteristics of the IR spectrum itself.

The light pipe with its KBr windows is the heart of the flow cell assembly. The inside of the glass light pipe is coated with gold to prevent the loss of IR light and provide as inert a surface as possible. The internal volume of the light pipe is approximately 100 µL with an i.d. of approximately 1 mm. Material eluting from the GC column enters one end of the pipe, passes through and exits the other end. As the material passes through the pipe, portions of the IR light are adsorbed, this phenomenon being captured by the detector.

Due to the relatively small diameter of the light pipe (1 mm), extreme care must be exercised in the proper alignment of the pipe itself, the parabolic mirrors of the IR light path, and the detector. All of these parameters can be optimized for maximum IR light throughput by monitoring the output of the detector while these objects are slightly moved. Maximum voltage output from the detector translates into more IR light throughput. Sequential adjustments of the objects will yield a maximum voltage indicating maximum IR light throughput. Once alignment is achieved, little to no further adjustments should be necessary.

Installation of the end of the GC column into the light pipe at the ideal position is essential for optimum performance of the GC/FTVPIR system. When the system is up and operational, IR light is continually passing through the pipe and causing the detector to output a certain voltage. Slow insertion of the end of the GC column into the light pipe from a side port can be made until there comes a point where the end of the GC column breaks the plane of the IR light beam, causing a change (drop) in the output voltage of the detector. The optimum position is, thus, the point of closest approach of the GC column end to the IR light beam without any interference. This location allows the GC column effluent optimum interaction with the IR light beam, thereby providing maximum sensitivity.

To obtain the necessary sensitivity from the IR detector, the mercury cadmium telluride IR detector must be cooled with liquid nitrogen. Most commercial systems provide IR detectors having Dewars capable of housing enough liquid nitrogen for 4 h. Thus, periodic checking of the detector liquid-nitrogen level is essential.

### 3.5 Gas Chromatography/Fourier Transform Matrix Isolation Infrared Spectroscopy

The successful operation of a gas chromatography/Fourier transform matrix isolation infrared spectroscopy (GC/FTMIIR) set-up depends on complete isolation of the effluent of a GC column at temperatures approaching...
10 K in an inert noble gas matrix. Complete isolation of the molecule in the matrix virtually eliminates all intermolecular interactions. In addition, molecular rotation is severely reduced at the very low temperature. Once captured at 10 K, usually in argon, maintenance of the temperature is fundamental to the success of the approach because the Fourier transform infrared spectroscopy (FTIR) spectra are gathered post-deposition. The availability of argon in which the analytes are captured is made possible by employing helium GC carrier gas containing approximately 5% argon. The presence of this small amount of argon in the GC carrier gas does not have any significant impact on the performance of the chromatography. At 10 K helium does not freeze and is hence pumped away via a diffusion pump–roughing pump configuration.

Figure 11 represents a simplified schematic of a GC/FTMIIR system. A description of the physical characteristics of the instrumentation is essential to a full understanding of the operation of the technology. The vacuum chamber denoted by the rectangle is fitted on top with a Pyrex window/O-ring for viewing the collection disk. The vacuum is provided by a diffusion pump and a roughing pump configuration. IR light from a Fourier transform spectrometer passes through specially designed windows as it reflects off a pair of dual parabolic mirrors, the collection disk, and a focusing mirror onto the surface of a mercury cadmium telluride detector. The detector must be cooled with liquid nitrogen. Positioning of the mirrors is very critical to the successful functioning of the GC/FTMIIR system. The optimum position of the multiple mirrors is accomplished in a way similar to the VP system by maximizing the voltage output of the detector under normal operating conditions. The optimization must take place under normal operating conditions because temperatures in the area of 10 K cause subtle changes in the position of the collection disk.

The collection disk is constructed of oxygen-free high-conductivity copper plated with hardened gold. The curved surface of the collection disk is highly polished to yield a uniform mirror finish. The surface of the collection disk serves as a platform for the collection of the effluent from the GC column from the GC transfer line. The effluent is the carrier gas, usually helium, containing about 5% argon as well as any analytes that may be present. When the effluent strikes the surface of the collection disk at 10 K the analytes and argon freeze on the disk and the helium is pumped away. Simultaneously, while the effluent is exiting from the transfer line, the collection disk is rotated at a predetermined rate. Thus, as the disk rotates the resultant physical phenomenon is a thin layer of argon on the surface of the collection disk. Close examination of this layer of argon reveals the presence of what appears to be a very fine transparent thread on the surface of the collection disk. Imbedded within the thread of argon are the analytes that have been separated by the GC column.

The position and characteristics of the GC transfer line relative to the surface of the collection disk are very important for the optimum deposition of the argon. The capillary GC transfer line protruding slightly from the heated nozzle (Figure 12) is made of deactivated fused silica of approximately 150 µm in diameter. The end of the GC transfer is positioned within approximately 150 µm of the surface of the collection disk. Incorrect positioning of the tip of the GC transfer line will result in an uneven/broken appearing thread of argon on the surface of the collection disk. More importantly, if the...
Figure 12 Drawing of the collection disk used in the GC/FTMIIR experiment showing the end of the GC transfer line protruding from the heated nozzle. Also illustrated is the argon thread. The dark marks in the thread indicated the position of solutes and correspond to the chromatogram at the bottom of the figure. (Reproduced courtesy of the American Chemical Society.)

tip of the GC transfer line is too close to the collection disk, contact between the two could result, scratching the surface of the collection disk. A scratched surface renders the collection of IR data impossible.

As the positioning of the collection disk is under computer control, the position of the disk relative to the IR light beam is always known. Thus, after a GC separation has been completed, exact positioning of the collection disk relative to the incoming IR light beam is possible. Analysis of the argon thread by FTIR takes place in the following way. The initial portion of the thread is scanned to establish a background. Then the disk is rotated at a predetermined rate while FTIR interferograms are rapidly taken and stored on the computer. After the entire run has passed under the IR beam, the data are converted into a plot of IR adsorption versus time. This plot is very similar to the Gram–Schmidt plot obtained from the Fourier transform vapor phase infrared spectroscopy (FTVPIR) experiment. The main difference is that in the FTVPIR experiment the data are collected in real time, whereas in the Fourier transform matrix isolation infrared spectroscopy (FTMIIR) experiment the data are collected post-run. To provide some assistance in determining the exact location of the argon matrix-trapped analyte on the collection disk, the instrumentation is fitted with an open split interface that allows a portion of the GC column effluent to be directed to a FID. The output from the FID is captured by the GC software, producing a trace of FID response versus time. The FID is a universal type of detector responding to most volatile and semivolatile organic compounds. Thus, the potential for correlating a FID response with an FTIR response is available with the instrumentation. The presence of retention times from the FID data also facilitates positioning of the collection disk directly under the IR beam such that the IR beam is focusing directly on the analyte of interest. For example, the response of hydrocarbons from the FID detector is normally relatively intense, at least with respect to the IR response that would be expected from a very low concentration of a hydrocarbon. Consequently, the FID would assist in locating components which may not possess strong IR-adsorbing chromophores.

Having captured the analytes in an inert noble gas matrix, coupled with the ability to hold them there for an extended time (hours), offers a distinct advantage to the matrix isolation (MI) experiment over the VP experiment. The VP experiment is a flow-through approach in which the IR data is gathered on the fly. In marked contrast, in the MI experiment the captured analytes can be examined over extended time. This capability translates directly into a tremendous improvement in sensitivity. Imagine possessing the capability of gathering IR spectra for as long as one wants. That is, the capacity for co-adding multiple numbers of scans of the analyte together with multiple scans of background spectra and subtracting the two. In practical terms this capability has afforded the capacity to collect FTMIIR spectra having excellent signal-to-noise ratios on as little as picogram quantities of material in a few minutes. Also, additional increases in sensitivity are realized because the lower temperature of the MI experiment versus the VP approach reduces the decomposition of thermally unstable molecules.

The lack of intermolecular interaction coupled with the virtual absence of molecular rotation, leads to IR absorption spectra from the MI experiment having significant and meaningful differences from IR spectra taken in other matrices. For example, narrow lines, frequently below 0.5 cm\(^{-1}\) for relatively small molecules, can be routinely obtained under MI conditions. Spectra such as these have been very useful in studying reactive molecules such as free radicals and reaction intermediates. Thus, the characteristics of the IR spectra obtained from an MI environment at extremely low temperatures would be expected to be very different from those obtained at elevated temperatures, such as VP experiments or even at room temperature. In the MI experiments, the ratio
of inert gas molecules to analyte molecules dictates the characteristics of the IR spectrum. This behavior is not unlike that observed as a function of concentration in solution room-temperature IR spectra. Acceptable ratios of about 5000 argon atoms to one analyte atom have produced excellent FTMIIR spectra using the GC/FTMIIR instrumentation.

Through a systematic investigation of a series of organic compounds possessing different functional groups, a relationship between the energy of selected band maxima as a function of matrix has been established. That is, the matrix in which the IR spectrum is taken significantly influences the energy and position of band maxima. For example, in the case of methyldecanoate carbonyl, absorption bands were observed at 1754, 1738, and 1769 cm\(^{-1}\) for the compound in an argon matrix, in the solid state, and in the VP, respectively. In general, the IR absorption maxima for compounds captured in an argon matrix were found to be intermediate between high values established by the VP experiments and low values established by IR spectra taken in the solid state. Likewise, statistically significant differences were also noted in IR absorption band maxima for organic compounds captured in a xenon or argon matrix. For example, the amide I band for diethylacetamide was found at 1661 cm\(^{-1}\) in a xenon matrix and at 1673 cm\(^{-1}\) in an argon matrix.

The virtual absence of molecular interaction and rotation in MI species afforded the capability of detecting a substantial difference in the IR spectra of \textit{cis} and \textit{trans} isomers in selected compounds. The elevated temperature of the VP experiment essentially eliminated any possibility of detecting this difference due to the relatively large widths of the absorption bands in the VP experiments. For example, the FTMIIR spectra of the \textit{cis} and \textit{trans} isomers of pinane were readily distinguishable one from the other.

### 3.6 Applications of Gas Chromatography/Fourier Transform Matrix Isolation Infrared Spectroscopy

Essential oils represent one of the more complex natural products having significant economic implications.\(^{(42)}\) Determination of the structure of the components in these oils is paramount to effective assessment of their potential. For example (\textit{\textminus})menthol, the major component of peppermint oil, is responsible for the major cooling effect known for peppermint. The other isomers of menthol, neomenthol, isomenthol, and neoisomenthol are structurally very similar to menthol but do not possess the cooling effect. GC/FTMIIR has been employed successfully to characterize the IR spectra of these compounds affording the capability to detect their presence in essential oils.

### 4 CONCLUSIONS

Within approximately two decades of the first coin- ing of the term “hy-phen-ated”,\(^{(1)}\) hyphenated capillary GC techniques have become the methods of choice for the qualitative and quantitative analysis of complex mixtures.\(^{(51)}\) Development efforts in modern GC-based instrumentation, depending on the integration of theories of GC, computers, and powerful information-rich techniques such as MS and FTIR detectors, have produced a wide array of very potent systems. Orchestration of combinations, such as on-line sample introduction, SPME, with GC, and MS, SPME/GC/MSD, has led to hyphenated systems with applications in a variety of areas. The enormous data sets generated from the information-rich detectors have been handled relatively easily with the advent of fast personal computers.

Future analytical hyphenated systems will most probably encompass the use of high-speed GC with accompanying high-speed mass spectrometers, infrared detectors and other specific detectors. Advances in hardware associated with on-line sample introduction approaches, such as SPME, LVI, MDGC, and HS techniques (dynamic and static) will assist in lowering further both the qualitative and quantitative limits of detection. Miniaturization of components should lead to additional systems being very compact and field deployable, with data transmission links directly to laboratory-based data analysis platforms. These advances should facilitate the collection of data followed by the rapid conversion of that data into information, and this new information into knowledge.

Instrumentation for gas chromatography (GC) comprises well-defined components, each of which contributes to the overall chromatographic performance. Most of these components have reached a mature level of technical development after nearly 50 years of development. Nonetheless, advances are occurring in an evolutionary, not revolutionary, manner with sample handling and in refinements of detectors. One area of dramatic advance in GC instrumentation is the development of small, sophisticated, portable gas chromatographs. Each component of a gas chromatograph (columns excepted) is discussed below where principles and recent developments are emphasized.

1 INTRODUCTION

The key parts of a gas chromatograph include: a source of gas as the mobile phase, an inlet to deliver sample to a column, the column where separations occur, an oven as a thermostat for the column, a detector to register the presence of a chemical in the column effluent, and a data system to record and display the chromatogram. In addition, some facility is needed so that temperatures of various components can be accurately known and controlled. These parts of a gas chromatograph have been unchanged in function or purpose for over the last 40 years although technology has been ever improving in design, materials, and methodology. In particular, analog electronics for control of temperature zones and data acquisition were replaced with digital electronics and interfaced with computers in the 1970s and 1980s. The arrangement of these components is shown in a block diagram in Figure 1 and this arrangement is common to virtually all gas chromatographs regardless of age, model or manufacturer. A modern gas chromatograph is shown in Figure 2. In the discussion below, the general function of each component is provided with comments on the status of the technology. Most descriptions of GC will include a cursory description of instrumentation; few will provide a detailed treatment of the instrumentation or technical details. Some of the best discussions of hardware can be found in publications released by instrument manufacturers\(^1\).\(^2\) Unfortunately, these may not be found routinely in libraries but the reward for efforts to obtain them is found in the useful details for optimizing an analysis or practical help for maintaining the instrument.

The column may arguably be considered the key component of a gas chromatograph and accordingly has been treated separately under another heading. However, the total variance of a separation (\(\sigma_T\)) will conform to principles of error propagation and be a sum of variances from the injector (\(\sigma_I\)), column (\(\sigma_C\)), detector (\(\sigma_D\)), and data system (\(\sigma_{DS}\)), i.e. \(\sigma_T = \sqrt{\sigma_I^2 + \sigma_C^2 + \sigma_D^2 + \sigma_{DS}^2}\). Thus, each of these components contributes to the overall efficiency of a GC separation and merits individual attention.

2 CARRIER GAS

The carrier gas or mobile phase in GC is an essential, but limiting, facet in separations. Carrier gas is the means to move constituents of a sample through the column and yet the choice of possible gases is restricted. Moreover, the carrier gas has properties that sometimes can complicate an analysis. Unlike liquid chromatography (where a wide selection of mobile phase compositions may be possible),
very little can be gained in separations through altering the mobile phase composition to influence the partition coefficient \(k\) or separation factor \(a\) in GC.

### 2.1 Selection of Gases

The choice of a practical carrier gas is simple: nitrogen or helium. Air may be used as a carrier gas under certain conditions with portable or on-site chromatographs but this is uncommon with laboratory-scale instruments. The choice of nitrogen or helium is made, in part, on the principles of separation and, in part, on economics: \(\sim$20 for a nitrogen cylinder versus \(\sim$50 for a helium cylinder. However, the selection is more complex than the prices of gas cylinders alone. Column efficiency in GC contains a term for contributions to longitudinal broadening in the carrier gas and this is given by the \(D_g\) term in the van Deemter equation.\(^{3}\) This term is proportional to the square root of molar mass for the carrier gas, and nitrogen or argon would be preferred over helium based on \(D_g\) only. This effect can be seen in Figure 3, where nitrogen provides better performance than helium and has the lower contribution to plate height. However, the shape of the curve for height equivalent to a theoretical plate (HETP) versus flow rate (as linear velocity) for helium shows a reasonably good efficiency at high flow rates.\(^{1,4}\) (HETP is equal to \(L/N\), where \(L\) is the column length and \(N\) is the number of theoretical plates in a column.) In contrast, the van Deemter curve for nitrogen is comparatively narrow. Consequently, a GC separation using nitrogen at \(10\) cm s\(^{-1}\) can be accomplished with comparable separating efficiency using helium at \(50–60\) cm s\(^{-1}\). The practical consequence of this is that costs for using helium, on a per sample basis, might be lower than those for nitrogen when the speed of analysis is factored into the calculations.

### 2.2 Control of Flow

One difficulty in GC is the compressibility of the carrier gas and subsequent influence on separating performance. This was recognized in the first paper on GC where correction factors for gas flow rates were described.\(^{5}\) The implications for isothermal methods are significant but will be critical with temperature programmed GC when column temperatures may span \(200^\circ\)C or more.\(^{6,7}\) When temperature is increased for a column with constant pressure on the inlet, the average flow rate in the column will decrease owing to increased viscosity of the gas mobile phase in a proportional but nonlinear manner. Under such conditions, flow rates may slow at high temperature and both separation speed and efficiency may suffer. Flow may be kept constant through mass flow meters that have inlet and outlet orifices, adjustable based upon pressure differences.\(^{2}\) Constant flow can be delivered across a range of pressure drops that may arise due to changes in temperature but cannot compensate for changes in barometric pressure. An advance in instrumentation during the past decade has been the commercialization of flow programming so that flows may be made highly reproducible.

### 2.3 Gas Sources and Purity

A common gas source for nitrogen or helium is the pressurized cylinder or bottled gas supply, readily supplied...
as a steel tank with a two-stage pressure regulator. This is still a common gas source though gas generators for nitrogen (air and hydrogen too) can be commercially competitive with bottled gas and have advantages in safety.

Regardless of the gas source, special attention must be given to the purity of tubing used to connect the source and the gas chromatograph and to impurities in the gas supply. Most columns do not tolerate moisture and oxygen well when operated at temperatures over 100 °C. Best results for column longevity and chromatographic reproducibility occur when the carrier gas is cleaned over molecular sieve beds (to reduce moisture). In addition, specialized traps can be purchased to reduce or remove hydrocarbons and oxygen in the carrier gas.

3 SAMPLE INLETS

The chromatographic process begins when sample is introduced into the column, ideally without disrupting flows in the column. The chromatographic results will be reproducible inasmuch as this is accomplished with a minimum of change in pressure or flow of the carrier gas or mobile phase. Also, the injection step establishes the initial (and best possible) peak width for the GC measurement. Thus, delivery of sample into the column should be controlled, reproducible, and rapid.

3.1 Syringes and Switching Valves

A common method for placing samples on a GC column is to use the microliter syringe with a needle to penetrate a plastic membrane. In this method a gas-tight seal is maintained and sample is deposited into a heated zone. If liquid or solid, sample is volatilized and swept to the column and this can be accomplished by manual injections in ~1 s. Syringe injection is a convenient and generally effective method though the thermoplastic septum develops leaks after repeated injections. Fatigue of the plastic septum limits the number of injections to ~30 before the septum must be replaced. A second difficulty arises with impurities from off-gassing or decomposition of the septum and these are seen as so-called ghost peaks or peaks in control blanks. (8)

Advances with capillary columns introduced unprecedented precision and accuracy to GC measurements and limitations with syringes became apparent. (9) Discrimination toward high boiling point components was seen with syringe injections and techniques to remedy the failings have been developed. (9) Sometimes thermal volatilization may lead to decomposition of samples so efforts to remove the discrimination and decomposition motivated the use of so-called on-column injections where sample is deposited directly from the syringe into the column. Another complication with syringe injections is the introduction of particulate and reactive materials into columns. Protection is afforded by precolumns. Further information on syringe injections and the range of options for injection methods can be found in excellent reference sources. (10, 11)

Gas samples can be injected into the column using gas-tight syringes or using rotary gas switching valves that offer enormous flexibility for GC instruments. (12) Precision gas switching valves allow a gas sample to be measured with a precise volume and introduced into carrier gas flow without interrupting column flow. Sample is loaded into a loop and then, with a change in the valve position, is swept into the column under flow of the gas source. Heated switching valves such as those made by VICI, Inc. (13) are also useful in the analysis of sorbent traps. When traps are heated and switched in-series with the analytical column, constituents will be thermally desorbed for GC separations. Switching valves can be automated via electronic actuators and can be incorporated into purge-and-trap methods that are useful for characterizing aqueous samples for volatile organic constituents.

3.2 Pyrolysis

Another inlet option which is now routine in certain specific applications of material sciences is that of sample pyrolysis where solid samples are rapidly heated to a point of thermal decomposition in a reproducible manner. At temperatures in excess of 600 °C, substances such as natural or synthetic polymers thermally decompose to small molecular weight, stable substances that provide a chromatographic profile which is unique to certain materials. Such an injector enlarges the application of GC to solid samples that would not normally be considered suitable for GC characterization, and pyrolysis methods have become standardized for some applications such as assaying plastics. A journal now exists for analytical applications of pyrolysis, the Journal of Analytical and Applied Pyrolysis. Attachments to inlets are commercially available and serve to extend GC in forensic and industrial applications, as shown in Table 1.

3.3 Other Topics

In purge-and-trap methods, a small amount of water is treated vigorously with an inert gas flow sufficient to sweep volatile organic compounds (VOCs) into the gas phase from the water phase. The gas flow, including the VOCs, is passed through an adsorbent trap where VOCs are retained and concentrated while water vapor and

Gas are unretained and released to vent. After a short time of purging, the trap is placed in series with the gas chromatograph via a gas switching valve and VOCs are transferred to the analytical column. This is done through a rapid increase in temperature of the sorbent trap and the vapors are carried to the analytical column under carrier gas flow. Purge-and-trap methods are the basis for an expansive use of GC for monitoring the VOCs at ppb levels in aqueous samples as specified by the United States Environmental Protection Agency (USEPA). Such instrumentation and methods are available today in commercial instrumentation and can be fully automated. An advantage in this method of sample preparation is that nonvolatile constituents, which could potentially foul the column, remain in the sample container and do not enter the column.

Another adaptation of GC for trace organic analysis was the development of solid-phase microextraction (SPME) with a syringe design. In this, a stationary phase is bonded on a silica fiber that can be introduced to a gas or aqueous sample. Organic chemicals partition into the coated fiber during a time of contact and the fiber is withdrawn into a syringe needle. In an injection port the fiber is pushed from the protection of the needle and sample is thermally desorbed into the GC column. This method has advantages of convenience and simplicity and the growth of use of SPME injections has been dramatic during the 1990s. A list of some representative applications is given in Table 2.

4 Ovens

4.1 Conventional Designs

Liquids or solids must be converted to vapor state and maintained as a vapor throughout the GC separation. Therefore, most gas chromatographs are equipped with ovens to keep the column at temperatures from 40 to 350°C. Exceptions are those chromatographs that are used in separating simple gases such as light hydrocarbons or permanent gases. Early gas chromatographs were equipped with isothermal ovens. Today, temperature-programmed ovens allow separations of chemicals spanning a range of vapor pressures in a single analysis.

Conventional ovens, unchanged in decades, consist of a resistive wire coil that radiates into the inner volume of the oven. Heat from the resistive wire source is spread, ideally in an even manner, throughout the oven volume using a fan attached to an electric motor. A thermistor or thermocouple inside the oven is part of regulating the oven temperature via the amount of heat released by the heating element. This is controlled by the power delivered to the element and a feedback circuit to control and program the oven temperature. Efforts to create isothermal conditions, i.e. no thermal gradients inside the oven volume, are essential for reproducible chromatography and are criteria in evaluating good oven designs. Gradients in excess of a few degrees between various regions of an oven are practical in the best of oven designs and can be more than a few degrees in poorly designed ovens. One of the only systematic evaluations of GC ovens was given by Welsh and his discussion provides measures for characterizing GC ovens.

4.2 Other Designs for Control of Column Temperature

Several alternatives to conventional ovens have been devised and may be especially helpful for short columns or instances where little space is available for a bulky, heated air oven. Two approaches have been used and include small thermal ovens and innovative column heating arrangements. Column heating based on resistive heating is compact, uses minimal power, and can decrease analysis times. These methods are based upon application of heat directly to the column or a base upon which the column is crafted or attached. The approach is unlikely to become a laboratory standard but is being explored for use in miniature or portable gas chromatographs.

5 Detectors and Data Systems

The subject of detectors in GC is a pivotal theme since the separation processes will have been wasted if the analyte...
cannot be detected. Excellent primers on GC detectors are available and any general text on instrumental analysis will have introductory material on the common detectors. A biennial review contains an extensive section on developments of GC detectors and can serve as a guide to primary literature.

5.1 Detectors

Effluent from the column enters a detector where the composition of the carrier gas stream is characterized through one of several possible chemical or physical properties of molecules. The mainstays in GC have been the flame ionization detector (FID), the thermal conductivity detector (TCD) and the electron capture detector (ECD). Other commercially available detectors include the photoionization detector (PID), the nitrogen–phosphorus detector and the atomic emission detector, though these have been less prevalent historically than the FID, TCD, and ECD. Other detectors have been introduced through the years but have never become widely used in GC methods. The FID relies upon the formation of gaseous ions from organic molecules combusted in a hydrogen–air flame; the TCD is based upon changes in the heat absorbing properties of the gas effluent when the carrier gas is altered with analyte; the ECD response is governed by the ability of some molecules to attract and remove thermalized electrons. Despite long-standing conventions for the design and operation of these detectors, advances still occur.

Examples of evolutionary changes include the small FID designs and designs where gas mixing is arranged to provide optimum response. A recurring theme in advances in ECD has been a nonradioactive alternative to the normal source, 10 mCi of $^{63}$Ni. Despite promising discoveries, the radioactive source is still the favored choice. The applications of ECD illustrate the advantages of selective detectors where analyte can be found in the presence of potentially interfering matrix.

Examples where the ECD was chosen to detect a specific chemical family over interfering backgrounds include: halocarbons in air for oceanographic tracer studies; chlorobutanol in mouse tissues and fluids; organochlorine compounds in milk products; pesticides and other organochlorides in water; organochlorine pesticides in edible oils and fats.

In the last two decades, inexpensive mass spectrometers or mass-selective detectors (MSDs) have dramatically transformed the practice of GC. Once the purview of laboratories able to sustain the high cost of mass spectrometers and the high level of maintenance, instrument manufacturers made mass spectrometers both robust and inexpensive. This development, when combined with the appreciation that analytical confidence is highest with a mass spectrometer as the detector, has resulted in a near general availability of gas chromatography/mass spectrometry (GC/MS) instrumentation. In a GC/MS analysis, a mass spectrum can be obtained continuously at fixed intervals of ~0.1 s throughout the analysis. Consequently, a mass spectrum can be obtained for each chromatographic peak and the shoulders and baselines in the chromatogram. No other detector can provide the richness of information available in such results. Detection limits can be enhanced through the use of single ion monitoring where the mass spectrometer is used for detecting the intensity of one or a few ions. This can provide the specificity of a mass spectral pattern for response without losses in detection limit associated with scanning over unused $m/z$ space. One revolution in the past decade has been the application of powerful desktop computers to control instrumentation and especially to control data acquisition and handling.

5.2 Data Systems

At a fundamental level, acquisition of chromatographic results has been little changed since the early days of GC, though the digital revolution has meant that strip chart recorders, once the mainstay of collecting chromatograms, cannot be found today and only electronic recording-integrators or microcomputers are used. Signal from the detector amplifier is digitized and stored to disk allowing enormous convenience in retrieving and replaying results. This means that peak retention times, peak areas, etc. are automatically reported and have been since the mid-1970s. In addition, software allows the results to be displayed in an automated manner, i.e. reports can be generated according to standard reporting formats. All this can be economically integrated into the total instrument control and management through computers and is an option on all chromatographs and a standard feature on most instruments.

6 MINIATURIZED, HIGH-SPEED, AND PORTABLE GAS CHROMATOGRAPHS

One area of GC that has shown vibrancy with advances during the 1990s is that of small, fast, and portable GC instruments. Though process gas chromatographs were amongst the first sophisticated analyzers placed into industrial on-site measurements, the subject has taken new significance following the burgeoning environmental movement. Making measurements where a sample is located rather than relocating samples to a centralized laboratory underlies this trend. Recently, a new journal
has appeared to support these efforts, Field Analytical Chemistry and Technology, which includes portable GC advances.

In high-speed GC, retention times can be pushed under a few minutes or seconds with short, narrow bore columns or high flow rates. Part of the challenge in fast GC is the compressibility of the carrier gas and the necessary speed (low time constants) for subcomponents such as injectors and detectors for high-speed separations.

6.1 Instrument Designs

An example of the size possible for small gas chromatographs is an ultimate miniature gas chromatograph created using silicon micromachining and integrated circuit processing techniques. This GC analyzer contains a 0.9 m long \( \times \) 300 \( \mu \)m wide \( \times \) 10 \( \mu \)m high rectangular column coated with a 0.2-\( \mu \)m thick liquid phase. The injector is a 10-\( \mu \)m-long sampling loop with the same cross-section as the column. Dual detectors based upon a coated chemiresistor and on thermal conductivity are used. The complete system is packaged in less than 23 cm\(^2\) and is 2.5 mm high. Although limited in scope to the detection of ammonia and nitrogen dioxide, this miniature chromatograph offers exciting possibilities for future field instruments.

One trade-off for high-speed GC is the loss of capacity due to the smaller diameter and shorter columns. Application of packed capillary columns in high-speed GC has been shown to improve capacity and selectivity while obtaining high-speed separation for light hydrocarbons. An alternative is the multicapillary column which improved capacity while maintaining the efficiency obtained with small internal diameter columns.

Injection techniques for high-speed GC must provide narrow bandwidths due to fast analysis time requirements without compromises in resolution. One means to accomplish this is through cryogenic inlets which provide narrow bandwidths and in some instances injection times can be shorter than 10 ms.

6.2 Detectors

Mass spectrometers might be considered ideal detectors and adaptations to fieldable gas chromatographs have been made. One design is the size of a standard size suitcase, weighs \( \sim 31 \) kg and uses \( \sim 600 \) W under peak loads. Naturally, field portability is a goal and man-portability has been demonstrated. A cart-portable unit has been described and was capable of screening 1000 samples an hour at a speed of 20–32 km an hour. Portable GC/MS instruments were also used for industrial hygiene applications. As the need for field measurements increases and mass spectrometry (MS) becomes miniaturized, the number of field portable GC/MS systems can be expected to increase dramatically.

Another sophisticated detector for GC is the ion mobility spectrometer and recently it too has been coupled to gas chromatographs for field analysis. The utility of this hand-held gas chromatograph/ion mobility spectrometer analyzer was demonstrated by rapid screening (\( \sim 20 \) s) with chemical warfare agents such as dimethyl methylphosphonate. One of the most impressive demonstrations was that from the US Army where a portable pyrolysis-gas chromatograph/ion mobility spectrometer was developed for screening airborne pathogens. This unit is shown in Figure 4.

This part of GC instrumentation may be expected to undergo continued development as interest in speed of analysis pushes dimensions and hardware. Therefore, it represents one of the few areas of growth in GC.

![Figure 4](image-url)
instrumentation that can be recognized in the absence of a revolutionary change in GC methods.

GAS CHROMATOGRAPHY

In gas chromatography (GC) the liquid phase, also called the stationary phase, provides the medium in which the separation occurs. The magnitude of separation is given by the relative strengths of intermolecular interactions between analyte and stationary phase molecules, thus numerous liquids have been used over the years. The stationary phase can be coated onto a solid support and packed into a tube (packed column GC), or coated onto the wall of a capillary (capillary GC). Today, most GC analyses are performed using capillary columns.

1 INTRODUCTION

In GC, the liquid phase, which is coated onto the inside wall of a capillary column, or onto solid particles in a packed column, is commonly referred to as the “heart” of the system, as this is where the entire separation occurs. Since the inception of GC, the design of columns and of liquid phases has undergone significant changes, but columns may still be classified into several distinct categories. If the stationary phase is a solid, the technique is termed gas–solid chromatography (GSC); if it is a liquid, then the technique is called gas–liquid chromatography (GLC). Packed columns arise from packing a tube, typically 6.3 or 3.2 mm (1/4 or 1/8 inch) in outside diameter with stationary phase particles that may or may not be coated with a liquid phase. Capillary or open tubular columns come in a variety of dimensions, from 0.05 mm to 0.53 mm in inside diameter and have a liquid or solid stationary phase coated onto the inside walls of the capillary. Capillary columns are generally used for applications that demand high resolution, trace analysis or high temperatures, while packed columns are generally used for applications requiring high sample capacity, ease of use and low temperatures. This article addresses liquid phase coatings for packed and capillary columns.

In any GC column, packed or capillary, the ability to achieve a separation depends upon specific interactions between the stationary phase material and the specific analytes, and upon the vapor pressure of the analyte. As a rule of thumb, GC can analyze any compound for which vapor pressure or boiling point data can be obtained by other methods. The specific interactions include dispersion forces, hydrogen bonding and weak electrostatic interactions. It is the need to modulate these interactions to produce a desired selectivity and the need for stable inert liquid phase materials that drives the development of new stationary phases. Column dimensions, such as length, tubing inside diameter, liquid phase loading and particle diameter for packed columns and length, tubing inside diameter, and liquid coating film thickness for capillary columns also have strong effects on separation capability.
2 THE ROLE OF THE STATIONARY PHASE

In contrast to liquid phase chromatographic separations, in which separating power is determined by both the mobile and stationary phases, in GC, only the stationary phase–analyte interactions determine the separation capability of a column. The mobile phase (carrier gas) acts only as a carrier of vapor phase molecules. Thus, in developing GC methods, the nature of the stationary phase is a primary consideration. Both the chemical nature of the liquid phase and the dimensions of the column make strong contributions to the capability to develop a separation. Because the mass of liquid phase present in a capillary column is about 1000 times less than in a packed column, and because packed columns are practically limited to about 0.3 m (12 feet) in length, while capillary columns may be 100 m long or more, there are significant differences in approach to method development, so these are treated separately. These dimensional differences lead to the many different types of separations that can be performed on capillary columns.

2.1 Solute–Stationary Phase Interactions

Analyte vapor pressure and the nonbonded chemical interactions that influence solubility are the chief contributors to retention in GC. Thus, if high selectivity is the goal of choosing a stationary phase, these must be considered carefully. The major forces involved in determining the strength of retention on a given column are:

- London forces, which are based on dispersion between molecules and generate the effective boiling point of the analyte sorbed onto the stationary phase;
- Keesom forces, which are dipole–dipole interactions between analyte and stationary phase molecules;
- Debye forces, which are induced dipole-induced dipole interactions between analyte and stationary phase molecules; and hydrogen bonding in which polar functional groups on the analyte molecules interact with similar groups on the stationary phase.

Of these, hydrogen bonding and London forces will provide the strongest interactions, while Keesom and Debye forces will be secondary. Thus, in choosing a stationary phase, structural similarity between the analyte and stationary phase, which for nonpolar compounds results in London forces and for polar compounds results in hydrogen bonding, should be the major consideration in determining the retention power of the stationary phase for a given analyte, or the selectivity for a given group of analytes.

The basic characteristics required of all GC stationary phases can therefore be summarized. First, the analyte must be soluble in the stationary phase material. In selecting a phase, “like dissolves like” is often sufficient for effective choices. Otherwise, considering hydrogen

RI, kovats retention index.

Packed columns were introduced in 1952 by Martin and James along with the first gas chromatograph.\(^1\) The vast majority of GC work in the 1950s–1970s was performed using packed columns, as capillary columns were prohibitively difficult to use for routine work at the time. Since the plate numbers of packed columns are limited, separation power was generated by novel stationary phase design, leading to the availability of hundreds of stationary phases and column designs. Today, use of packed columns is more limited, as capillary columns, with their high plate numbers and improved analytical sensitivity, have become routine.

Capillary, or open tubular columns, introduced in the late 1950s, were originally made of glass or stainless steel and were very difficult to use. In 1956, Golay\(^2\) described the tremendous potential benefit of the open tubular arrangement. However, capillary columns saw relatively little routine use over the next 25 years, as the glass columns commonly in use were very difficult to make, install into instruments and easy to break. In 1979, Dandeneau and colleagues invented the fused silica capillary columns in use today.\(^3\) Since then, capillary column manufacture and use has increased dramatically, capturing approximately 80% of the GC column market.\(^4\) Immediate benefits were seen, as routine high-resolution trace analysis became possible. Table 1 provides a brief time line of major developments in GC liquid phase technology.
bonding and other intermolecular interactions between analyte and stationary phase is required. Second, if more than one component is present in the mixture, the differential solubility, which determines selectivity, of the analytes in the stationary phase must be high. Physically, the stationary phase should exhibit low vapor pressure, so that it can be operated at high temperatures and should have low viscosity at lower temperatures. These variables will be addressed further in sections 3.5 and 4.3, for packed and capillary columns, respectively.

In the 1960s, much work focused on the characterization of the many stationary phases then available for packed columns. The classic work performed by Kovats, Rohrschneider and McReynolds provided much of the basis for future developments in column chemistry. Also, in the 1970s and 1980s, quality tests developed by Grob, Grob and Grob and others, continued to provide insight into column chemistry and performance. The Grob tests are addressed further in section 5.3. In order to compare chemistry among diverse stationary phases, a common means for recording retention times that accounted for variations on operating conditions was required. The Kovats retention index (RI) was the first of these. Retention times of the n-alkanes are used as standards and the retention times of other compounds are calculated by Equation (1):

$$RI = 100N + 100 \frac{\log t_R(an) - \log t_R(N)}{\log t_R(N + 1) - \log t_R(N)}$$

where RI refers to the retention index of compound “an”, N refers to the number of carbon atoms in the normal alkane eluting immediately before the analyte and N + 1 refers to the normal alkane eluting immediately after the analyte; $t_R$ refers to the adjusted retention time. This was modified for linear temperature programs (Equation 2):

$$RI = 100N + 100 \frac{t_R(an) - t_R(N)}{t_R(N + 1) - t_R(N)}$$

This form of relative retention calculation results in a retention index that allows retention to be reported free of minor instrumental variations and variation in column dimensions. The Kovats indices also provide retention values that are directly proportional with the free energy of the bulk solute–stationary interactions. Thus, direct retention comparisons can be made between columns with differing dimensions and liquid phases. Tables of retention indexes have been published. Several other authors have developed alternative retention index systems, but the Kovats system remains most widely used.

Using the retention indexes of selected compounds (test probes) Rohrschneider and McReynolds developed schemes for assessing the chemical characteristics of GC stationary phases. A summary of the test probes used by McReynolds and Rohrschneider is shown in Table 2, along with the chemistry being measured by each test probe. Both McReynolds and Rohrschneider chose squalene, the liver oil of sharks, a nonpolar mixture of long chain, highly branched hydrocarbons, and one of the classical GC liquid phases, as a standard liquid phase. First, they measured the RI of each test probe on squalene. Next, for other phases, they measured the RI under identical conditions. The McReynolds constant for the new phase is given by the difference in RI for the test probe on the new phase versus squalene. For example, a high McReynolds constant for benzene indicates a column that will strongly retain compounds that are likely to undergo induced dipole interactions, such as other aromatics and olefins. Table 3 shows McReynolds constants for some common stationary phases. Today, column vendors and others who report stationary phase characterization data still report Rohrschneider–McReynolds constants. The structures and chemistries of these stationary phases are defined in more detail in sections 3.6 for packed columns and 4.4 for capillary columns.

### 2.2 Important Separation Variables

As can be noted from the above discussion of McReynolds constants, there are many variables related to retention and flow in columns that are important in any discussion of stationary phase characteristics. Thermodynamics of the phase transfer between mobile and stationary phases mostly determines the retention time of any analyte. This is most easily expressed as the standard free energy change, $\Delta G^*$ of the partitioning process between the mobile and stationary phases. The partition coefficient,

DEGS, diethyl glycol succinate.

\[ K_p = e^{-\Delta G^*/RT} \]  

(3)

Which leads to the retention factor (Equation 4):

\[ k = \frac{K}{\beta} \]  

(4)

And to the retention time (Equation 5):

\[ t_R = t_m(1 + k) \]  

(5)

The value of the standard free energy is given by the specific stationary phase–analyte combination. This derivation is reviewed in more detail by Snow(16) and forms the basis for the many efforts to predict retention times from thermodynamic data.(17–19) These thermodynamic arguments are the same for both packed and capillary columns, with the major difference being that phase ratios (\( \beta \)), the ratio of gas phase volume to liquid phase volume within the column, for capillary columns are generally 1–2 orders of magnitude larger than for packed columns.

Not only does the identity of the stationary phase determine the retention time, but the dimensions of the column have a profound effect on the retention time and the peak width, and ultimately the chromatographic resolution of closely eluting peaks. A summary of the important variables and their effects is given in Table 4. The master resolution Equation (6), as described by Purnell(20) also provides a useful summary, as high resolution is the goal of most chromatographic method development.

\[ R_s = \left( \frac{k}{1 + k} \right) \left( \frac{\alpha - 1}{\alpha} \right) \left( \frac{\sqrt{N}}{4} \right) \]  

(6)

Terms relating to retention \( k/(1 + k) \), selectivity \( (\alpha - 1/\alpha) \) and system efficiency \( (\sqrt{N}/4) \) are seen to each contribute to the overall resolution. Two peaks with \( R_s = 1.5 \) are said to be "baseline resolved". According to this equation, for the largest resolution to be achieved in the shortest time, \( k \), which is highly temperature dependent, should vary in the relatively tight range of 2–20, with little return seen in raising \( k \) above 20. \( N \) and \( \alpha \) will vary greatly according to the column type, dimensions and stationary phase. Using the master resolution equation, van Deemter and Golay equations, packed and capillary columns can be examined separately and compared.

2.3 Packed Columns

As discussed in section 3 of this chapter, the length of a packed column is limited by the inlet pressure that can be practically generated by the gas chromatograph, leaving typical lengths in the 6–12 foot range. Limiting the column length also limits the number of theoretical plates, with typical values for a 6.3 mm (1/4 inch) outside-diameter column being 6000–10 000 theoretical plates. The master resolution equation (Equation 6) can be used to describe the requirements for a column. If a desired resolution of 1.5 is assumed and that “normal” chromatographic conditions include $k$ from 1–20 and $N$ from 1000 to 10 000, the selectivity required to achieve a resolution of 1.5 is easily calculated by rearranging the master resolution equation. Table 5 shows the results of such a calculation using the master resolution equation, solved for selectivity. It is seen that selectivity greater than 1.064 is needed to achieve baseline resolution in the best case for packed columns, while for most packed columns, the necessary selectivity is higher. Since selectivity in GC is entirely based upon the nature of the solute–stationary phase interactions, the choice of liquid phase is critical in the development of nearly every method. This has led to the development of a very wide variety of liquid phases for packed columns, which are treated in more detail in sections 3.5 and 3.6.

Peak widths in packed columns are related to the height equivalent to a theoretical plate (HETP or $H$), which is described by the van Deemter equation (Equation 7) (21):

$$H = 2\lambda d_p + \frac{2\gamma D_M}{\mu} + \frac{q k d_k^2 \mu}{(k+1)^2 D_s}$$  (7)

The variables are described in the list of symbols at the end of this article. Many of the terms in this equation are related to the nature and dimensions of the liquid phase. The diameter of the stationary phase particles affects eddy diffusion in the first term, with larger particles generating larger $H$. Mass transfer in the stationary phase is affected by the diffusivity of the solute, indicating that less viscous liquid phases will provide lower $H$, as will a thinner film of liquid (smaller loading). The film thickness has the most dramatic effect, as it is squared.

2.4 Capillary Columns

Due to their length (10–100 m), capillary columns have much higher plate numbers than packed columns. In terms of generating resolution, therefore, the necessary selectivity for capillary columns is significantly less than for packed columns. Table 5, above, also shows the calculation of the necessary selectivity required to achieve a resolution of 1.5, for capillary columns, assuming retention factors between 1 and 20 and plate numbers between 10 000 and 500 000, typical values for capillary columns. It is seen that lower selectivity values, 1.012 (compared with 1.064 for the packed column described above) for $k = 20$ and $N = 250 000$, are needed than for packed columns. Thus, in the initial developments, there were far fewer liquid phases available for capillary columns than for packed columns. As stationary phase selectivity is less critical in the achievement of separation.

The Golay equation (22) (Equation 8) can be used to describe HETP for capillary columns.

$$H = 2D_M \mu + \frac{1 + 6k + 11k^2}{24(1 + k)^2} \frac{r_s^2}{D_M} + \frac{2kd_k^2 \mu}{3(1+k)^2 D_s}$$  (8)

It differs from the van Deemter equation in that, since a capillary column is an open tube, there is no term for eddy diffusion and since there is a much greater relative amount of mobile phase in a capillary, there is an additional mass transfer term for the mobile phase. The major variables that are affected by the liquid phase are the diffusivity of the solute in the liquid phase, indicating that low viscosity liquid phases are desirable, as are thin films. Again, the film thickness has the most dramatic liquid phase-related effect on $H$ and therefore, on the peak width.

2.5 Comparison of Packed and Capillary Column Separations

Chromatograms showing packed and capillary column separations of a polychlorinated biphenyl standard that demonstrate the characteristics of each resulting from the above theory are shown in Figures 1 and 2. About 15 peaks are shown in the packed column separation, which demonstrates about 1500 theoretical plates. The capillary column separation shows about 60 peaks and about 100 000 theoretical plates. Both separations were conducted isothermally, with the same liquid phase. Thus, with the same selectivity, the capillary column provides sharper peaks with much greater resolution in a similar analysis time. The greater mass of stationary phase in the packed column also requires higher elution temperatures and a slower analysis time, with much greater consumption of carrier gas and lower sensitivity.

The selectivity factors, as described above and calculated in Table 5 have a dramatic effect on the separation power of a column. For example, if $k = 5$ and
they proved difficult to make and use, so work in GC continued with packed columns. Today, about 80% of all work in GC is done with capillary columns; however, packed columns are still the method of choice for those analyses requiring the relatively large volume of liquid phase present in packed columns, such as fixed gases, solvents and other analyses in which partition coefficients are low, yet strong retention is required.

3.1 Tubing Materials and Dimensions

Typically, packed columns are 6.3 or 3.2 mm (1/4 or 1/8 inch) in outside diameter and 0.6–3.6 m (2–12 feet) long. Glass and stainless steel are the most common tubing materials, although nickel, Teflon®, copper, Teflon®-lined stainless steel and aluminum are also used. Copper and aluminum columns can be easily made in the laboratory from straight tubes, which can be bent to fit the instrument configuration, while the other materials must be purchased in the correct configuration for the instrument into which they will be installed. Figure 3 provides a summary of some common configurations used by major instrument manufacturers.

3.2 Solid Supports

In a packed column, the liquid phase must be coated onto a solid support material. Ideally, the support material should be capable of withstanding the physical stresses in GC, including high temperatures (up to 350°C, generally) and moderate pressures (up to 5 atm), should be inert and not react with sample components or liquid phase materials and should be readily available in a variety of mesh sizes. The important physical properties include particle size, porosity, surface area and packing density. Smaller particles will provide more plates, as shown by the van Deemter equation, yet will require a higher

Figure 3 Packed column tubing configurations (a) Hewlett Packard 5890, 5880, 6890; (b) Perkin Elmer 8300, 8400, 8500, 8600, 8700, auto system; (c) Shimadzu GC14A, GC15A, GC16A; (d) Varian 3300, 3400, 3700, Vista Series.

3 PACKED COLUMNS

Most of the early work in GC was performed on packed columns. Following the invention of the capillary column,
pressure drop, necessitating a shorter column. A larger surface area, which is determined by the porosity, will require more liquid phase to achieve a complete coating. Diatomite supports, graphitized carbon blacks and, to a lesser extent, Teflon® are commonly used. Each of these has advantages and limitations, which are governed by their physical properties and by their surface chemistry.

Diatomite supports are all derived from the various forms of diatomaceous earth. Firebrick supports are obtained by heating, grinding and pulverizing bricks; filter aid supports are obtained by adding sodium carbonate to diatomaceous earth and heating to obtain an aggregate that is generally more inert than firebrick; and Chromosorb G is a filter aid support that has been additionally heat treated to generate more durable particles. Each of these may be further treated with a silylating reagent such as dichlorodimethyl silane (DMDCS), to cover active silanol functionalities on the surface, or may be acid or base washed to remove any active metal contaminants. It should be noted that silanized supports are very sensitive to hydrolysis by water, so care should be taken to eliminate water from any methods where they are used. Acid or base washing is used to eliminate reactive metals such as iron from the surface. These can act as Lewis acids and participate in the decomposition of liquid phases and analytes. Table 6 provides a reference to the common solid supports used for GLC.

The firebrick supports Chromosorb P and Gas Chrom R are pink in color and are very strong particulates, with dimensions as shown in Table 6. These have very high surface area and can accommodate liquid phase loading of up to 30%. As their surfaces contain active silanols, they are typically reserved for the analysis of nonpolar analytes, although they can be deactivated for analysis of polar compounds. The white calcinated supports, Chromosorb W, Gas Chrom Q and Supelcoport, for example, are preferred for polar analytes, although they are more fragile and accept slightly lower liquid loading (ca. 25%). Chromosorb G is denser and more durable than Chromosorb W, but can only accept about 5% loading of liquid phase.

Other materials, such as carbon black and Teflon® have been used as solid supports for gas liquid chromatography. Teflon® is typically used for the analysis of small polar molecules, such as water, acids, amines, alcohols, and other compounds that may be corrosive to diatomite supports. Teflon® has a relatively low upper temperature limit of about 250°C and may develop static charges, making packing difficult. Carbon black is used as both an adsorbent and as a solid support. As a solid support, it allows for a combination of separation due to the liquid phase and the surface properties of the support, which separate according to the size and shape of the molecule. These are typically used for difficult separations of small molecules.

3.3 Packing and Preparing Packed Columns

Packed columns may either be purchased pre-made from a vendor, or they may be prepared in the laboratory from the appropriate length and diameter of tubing and the bulk packing material. Most common liquid phases are available precoated onto the solid support. When coating a liquid phase onto a solid support, first, the appropriate mass must be determined from the desired loading. There are three common methods for coating liquid phases onto solid supports:

1. Rotating Evaporator Method. The appropriate mass of liquid phase is dissolved in a suitable solvent in a round-bottomed flask and the weighed solid support is added. The solvent is then evaporated by rotary evaporation at reduced pressure.
2. Pan Coating Method. The liquid phase is dissolved in just enough solvent to wet the solid support and the Table 6 Characteristics of selected solid supports for packed column GLC. solution is added to the solid in a pan. The solvent is allowed to evaporate with gentle agitation and heat.

3. Funnel Coating Method. 20 g of solid support is added to 100 mL of liquid phase solution in a filter flask. The flask is placed under vacuum for a few minutes. The pressure is released and the mixture is placed in a sintered glass funnel and vacuum is applied for several minutes. The resulting solid is allowed to air dry.

More details on the coating of solid supports can be found in Barry.²⁴

Glass and stainless steel tubing comes pre-shaped to fit into the instrument’s fittings; copper and aluminum tubing can be bent into the appropriate shape. The pre-shaped tubing is available for a wide variety of vendors’ instruments and column lengths. To pack the stationary phase into a 6.3 or 3.2 mm (1/4 or 1/8 inch) outside-diameter tube, a funnel, with a short piece of Tygon tubing, a small amount of glass wool and an electric engraving tool are needed. Plug one end of the tubing loosely with glass wool, and using the funnel, connected to the other end by the Tygon tubing, add the stationary phase. Vibrate the tubing and add stationary phase until no more can be added. Plug the open end of the column with a small piece of glass wool, leaving the appropriate length for the GC inlet and syringe needle unpacked. Following packing, the column should be installed into the instrument, carrier gas flow established and should be conditioned for several hours at a temperature 25°C above the maximum temperature at which it will be used, but below the maximum temperature of the liquid phase.

3.4 Instrumentation Requirements

There are several instrumental considerations in the use of packed columns. First, the flow systems, inlets and detectors should be able to accommodate high carrier gas flow of 50–100 mL min⁻¹. On-column, direct, or gas valve injection are most commonly performed on packed columns, as syringe needles will easily fit within 6.3 or 3.2 mm (1/4 or 1/8 inch) tubing, and valve pneumatics are easily connected. This does provide the advantage of quantitative sample transfer into the column, without the use of splitters or special syringes, which are required for capillary columns. Packed columns have high thermal mass, requiring a very powerful oven heater and cooler if temperature programming is desired. This high thermal mass makes isothermal operation most common with packed columns. Due to the high flow rates, detector cells also are large and have high thermal mass, to maintain temperature equilibrium. In packed column gas chromatography/mass spectrometry (GC/MS), splitting devices must be used between the column and the detector, in order to reduce the flow entering the mass spectrometer sufficiently. Instrumentation for packed column GC is described in detail in Instrumentation of Gas Chromatography and in McNair and Miller.²⁵

3.5 Choosing a Stationary Phase

As shown in section 2 of this article, the relatively low plate counts of packed columns make the choice of liquid phase critical in packed column gas liquid chromatography. As a result, hundreds of liquid phases have been used over the years. A 1968 survey indicated 179 commonly used liquid phases. A 1997 vendor catalog lists 138, so a dizzying array of stationary phases remains available. Practically, it is not advisable to attempt to choose between all of these liquid phases; it is desirable to have a few choices that will solve most separation problems. The old maxim “like dissolves like” can provide a good start, as, from the discussion of stationary phase characterization presented above, it is difficult to develop a systematic scheme for choosing packed column liquid phases. Consulting the literature or the vendors’ application notes is also a good place to start. Recently, Supelco has made a compendium containing over 200 of the packed column separations available.²⁹

If consulting the literature does not provide a reasonable choice, then the McReynolds constants provide a starting point, as they measure the likely selectivity of the liquid phase for compounds similar to the test probes. For example, a liquid phase with a high value for the constant for n-butanol, would be a good choice for separating alcohols or other compounds expected to undergo hydrogen bonding. McNair and Miller have provided a general summary of recommended stationary phases compiled by several workers, which is shown in Table 7. It is seen that these cover a wide range of polarities, and with appropriate temperature control, can achieve most separations. A nonpolar column is always included, as are several of moderate polarity, along with a highly polar silicone and

FAME, fatty acid methyl esters.

Finally, once a potential liquid phase is chosen, the upper and lower temperature limits must be considered. At the upper temperature, the stationary phase itself has significant vapor pressure and will bleed from the column, reducing efficiency and shortening column lifetime. At the lower temperature, which may be the freezing point or glass transition temperature of the polymer, separation is also lost, as analytes no longer penetrate into the solid stationary phase.

### 3.6 Guide to Packed Column Gas Chromatography

#### Liquid Phases

A few of the most commonly used packed column stationary phases are described above. There are, however, myriad stationary phases available. Table 8, while not all-inclusive, provides a more extensive listing of common stationary phase materials and applications.

### 4 CAPILLARY COLUMNS

Capillary columns were first developed by Golay in 1957, shortly after the initial development of GC. Theory predicts that the narrow, open-tubular format should provide very efficient transport of analyte molecules along the column length, and therefore, very sharp peaks. The initial glass capillary columns saw little routine use, however, as the glass columns had to be hand-drawn from larger tubing using an expensive drawing apparatus, and once made, were very fragile. In order to install a typical, helical glass column into an instrument, the glass first had to be straightened by heating, so that the appropriate compression fittings could be installed. Capillary GC has flourished since the development of the fused silica capillary column by Dandeneau and colleagues in 1979. This development provided capillary columns that were
easy to handle and use. Other materials, such as stainless steel, aluminum cladded fused silica and Teflon® have also been used to make capillary columns for specific applications. The specific properties of these columns, as they relate to the liquid phase contained within them and to the development of separations, are discussed below. This section will also address the selection of appropriate capillary columns and stationary phases, along with a guide to stationary phase selection.

4.1 Design and Manufacture

Fused silica capillary columns are manufactured using optical capillaries with internal diameters commonly ranging from 0.100 mm to 0.530 mm, and with column lengths from 10–100 m. Smaller internal diameters are used for a few high-speed applications. The tubing is usually prepared by drawing a long length (hundreds of meters) using a drawing machine, which is then cut to the desired length after coating with the stationary phase. The fused silica tubing is coated on the outside with a polyimide that provides flexibility and tensile strength, along with the characteristic brown color. Users of capillary columns should be warned to wear safety glasses at all times when handling columns that are coiled, as the coils can unwind with such force that a column end can damage the eyes. Fused silica capillary tubing is prepared by extruding larger diameter tubing in a furnace, with the drawing process controlled by an infrared laser beam. Following drawing, the tubing is coated with a polyimide that provides flexibility, protection against water degradation and corrosion. The polyimide coating is stable to approximately 400 °C. For applications requiring temperatures higher than 400 °C, aluminum clad columns, in which the outer polyimide coating is replaced with a thin (ca. 20 µm) coating of aluminum can be used. These are commonly used in the separations of waxes, oils and triglycerides. Stainless steel has also been used as an outer coating for high-temperature work. The main advantage of stainless steel coating is that the column can be coiled very tightly, allowing it to be used in a small space.

Once the capillary tubing has been manufactured, it must then be prepared for coating, and coated with a thin (0.1–5 micron) film of liquid phase. The main requirements are the same as for packed columns: the column wall should be inert to the analytes and should allow the liquid phase to coat evenly. Classical coating techniques have involved the simple coating of polymeric liquids to the inside walls of the capillaries. More recently, the polymer has been chemically bound to the capillary wall. Prior to coating, the fused silica tubing must be deactivated, typically by reaction with silylating reagents. In 1985, Blomberg and Markides34 presented a thorough discussion of organo-silicon chemistry for capillary columns, including a discussion of pretreatments. The techniques include D4-deactivation, in which the capillary is coated with octamethylocyclotetrasiloxane (D4), sealed and heated to 400 °C, and the capillary heating with an appropriate polysiloxane, high temperature silylation using hexamethyl disiloxane (HMDS), and reaction with disiloxanes.

Once the capillary inside surface has been deactivated, it must then be coated with the liquid phase polymer. A stable, thin (0.1–5 micron) and uniform coating is needed. Coating procedures were reviewed by Jennings with the most common method being static coating. In static coating, first described by Bouche and Verzele, a solution of known concentration of the liquid phase is prepared in a volatile solvent. One end of the column is sealed and a vacuum is applied to the other end. Evaporation of the solvent leads to the deposition of a uniform coating of the less volatile liquid phase on the column wall. This method allows an accurate determination of the volume of stationary phase added to the column, and therefore the film thickness. Newly prepared capillary columns are then coiled into a circular metal cage to protect the column and to simplify mounting into the instrument oven. The chromatographic performance of a newly produced column can be evaluated using a column test mixture, as described later in this article.

4.2 Instrumentation Requirements

The specifics of GC instrumentation are discussed elsewhere in this Encyclopedia, however, there are several considerations that are directly related to the low carrier gas flow rates, small quantity of stationary phase, and open tubular nature of capillary columns. First, as shown by the Golay equation, the carrier gas flow rate is critical to the optimum performance of capillary columns, and should be adjusted carefully. Second, the small quantity of stationary phase, requires that analyte mass also be small, typically of the order of nanograms–picograms. Higher analyte quantities can overload the stationary phase, causing multiple retention mechanisms and distorted peaks. The open tubular nature of capillary columns indicates that the inlet–outlet pressure drop will be significantly less than for a packed column of the same length, allowing for very long (100 m is common) columns and high plate numbers. Column oven temperature control is also critical to optimum performance, as capillary columns, due to their low thermal mass compared to packed columns, are much more easily and rapidly temperature programmed. Thus the column oven itself should be of low thermal mass and be thermally insulated from other heated portions of the instrument. Most modern GC
Ovens employ forced air convection for rapid heating and cooling of the capillary column. More details on instrumentation for capillary columns are provided in *Instrumentation of Gas Chromatography* and in several references.\(^{41,42}\)

### 4.3 Choosing a Liquid Phase

Selecting a stationary phase for capillary GC is done using a similar thought process as for packed columns, but there are far fewer liquid phase choices readily available. First, there is a wide variety of literature available in both the research literature and in vendors’ publications; this is an excellent place to start. One vendor provides a compact disk\(^{43}\) compilation of over 1300 application notes, while several have application notes posted to searchable pages on the World Wide Web.\(^{44-48}\) If the literature fails to produce a satisfactory result, then the “like dissolves like” principle may apply to the stationary phase choice.

In capillary GC there are several liquid phases that are most commonly used, plus myriad phases for specialty applications. Barry\(^{49}\) provides a summary of general applications for the most common stationary phases, which is shown in Table 8. Chemical structures for the common stationary phases used in capillary GC are given in section 3.5. Since capillary columns generally have much higher plate counts than packed columns, the stationary phase choice can be much simpler. For most applications, a nonpolar phase such as polydimethylsiloxane (OV-1) or 5% phenyl polydimethylsiloxane (SE-54) can be used. More polar columns are used for specific applications, as shown in Table 8.

As the initial tool in a method development scheme, a moderate length (15–30 m) capillary column with a nonpolar stationary phase, such as polydimethylsiloxane or 5% phenyl polydimethylsiloxane, with internal diameter 0.2 or 0.25 mm and film thickness of 0.2–0.5 micron is recommended. This represents a compromise between analysis speed, high resolution and sample capacity. Once the temperature and flow conditions for a separation have been optimized as much as possible on this column, an alternative stationary phase can be selected, if the separation is not satisfactory. Klee\(^{50}\) and Klee and Kaiser\(^{51}\) provide systematic methods for selecting and optimizing capillary columns.

### 4.4 Guide to Stationary Phases for Capillary Gas Chromatography

Perhaps the most confusing part of stationary phase selection for capillary GC is that the many vendors use different designations for stationary phases that are essentially similar. A listing of the most common capillary GC stationary phases, obtained from a survey of vendors’ catalogs is given in Table 9, along with a cross-reference of major vendors’ designations.

5 CARE AND MAINTENANCE OF GAS CHROMATOGRAPHY COLUMNS

In both packed and capillary column GC, increasing tailing of one or more of the peaks in an analytical run, over several separations, most likely indicates degraded column performance. Depending on the types of samples being analyzed, a column may last for as little as 50–100 injections, or for several thousand. In any case, there are some general considerations in extending column lifetime, which are discussed here. For a more thorough treatment, see the monograph by Rood for capillary GC and see the troubleshooting guide presented by Supelco for packed columns.

5.1 Packed Columns

In general, packed columns are very rugged and easy to maintain. This is a result of the large mass of liquid phase that is present. Packed columns are more resistant to dirty solvents, or corrosive solvents, such as water or wet samples. Packed columns should be stored with the ends capped, to prevent oxidative damage over time. When they are installed into the GC, care should be taken not to overtighten the compression fittings, or leaks can result. When installed into the instrument, a gentle flow of carrier gas should be maintained at all times, to avoid oxidative damage to the stationary phase. When the liquid phase is becoming degraded from use, tailing peaks usually result. It is good practice to maintain a regular schedule of analyzing a known standard of an active analyte and to keep a record of the results. When this peak shows significant distortion over a period of several trials, column maintenance is necessary. In a glass column, discoloration of the first few centimeters of the stationary phase can sometimes be seen.

Usually, contaminants, such as nonvolatile material or contaminants irreversibly adsorbed onto the liquid phase, are found within the first few inches of the column. It is acceptable to carefully remove the glass wool plug, pour out the first few centimeters of stationary phase and to replace it with fresh packing. Tap the column gently on the benchtop or use a vibrating engraving tool to ensure even packing. Replace the glass wool plug with fresh glass wool, as this is a common source of contamination, and condition the column, as described for a new column. If the peak distortion persists, then the entire column packing needs replacement.

5.2 Capillary Columns

Capillary columns require more careful handling than packed columns, as there is a much smaller quantity of stationary phase present. In general, they should be stored with the ends sealed, to avoid oxidation of the stationary phase. Inserting the ends into a used septum makes an excellent seal, or they can be flame sealed. Wear safety glasses at all times when handling capillary columns, as the glass capillary ends can spring out and damage the eyes upon contact. Carrier gases should be free of organic contaminants and water, as these can also foul and contaminate the column. Typically, this requires a minimum of a molecular sieve trap to remove water and low molecular weight organic compounds and an activated carbon trap to remove higher molecular weight organic compounds. Heated gas purifier systems, available from several vendors, can also be used. The trapping material should be replaced or regenerated on a regular schedule. Carrier gases should also be high purity to avoid column and instrument contamination. Carrier gas flow should be maintained at all times that the column is installed into the gas chromatograph, to avoid oxidative damage to the stationary phase. It is good practice to leave the system running continuously, with carrier gas flowing and all zones heated to above ambient temperature. Most modern gas chromatographs have a “gas saver” feature to prevent excessive gas usage while samples are not running.

Tailing of peaks that were not previously tailing indicates column degradation. This diagnosis is more difficult in a capillary GC system than in a packed column system, as the column is typically separated from the inlet, where contamination is likely to occur. Thus, inlet contamination should be ruled out as the cause of tailing or distorted peaks, before column contamination is considered. As with packed columns, the contamination typically occurs within the first few centimeters of the capillary. If column contamination is suspected, the easiest treatment is to cut the first few centimeters from the column and discard it, and then to re-install the column into the gas chromatograph. Be careful to follow the manufacturer’s directions for cutting and re-installing the column, or the contamination can be made worse. Usually, this cutting procedure can be applied several times, before too much cutting reduces column performance. When installing the column, take care to avoid sharp bends in the tubing and contact with the oven wall or wire cage hanger. These can cause stress points or hot spots that can lead to breakage, leaks or stationary phase degradation.

Before using a column, the minimum and maximum operating temperatures, which are usually listed in the accompanying literature, should be checked and the column should not be operated below the minimum or above the maximum temperature. Below the minimum temperature, the polymer may solidify or become glassy, preventing absorption of analyte molecules and adversely impacting retention. As the maximum temperature...
is approached, the stationary phase itself begins to decompose, leading to vaporization of the decomposition products. These appear as a rise in the baseline, known as column bleed. At temperatures exceeding the maximum temperature, the column bleed becomes excessive and can damage the column or detector. Approximate maximum temperatures for common stationary phases are provided in Table 8.

The brown polyimide coating also deserves mention, as it gives the capillary column its tensile strength and flexibility; however, it, too can degrade over time. Usually, a darkening of the brown color indicates this. Beware that the column may become brittle and easily break at continuously heated zones, such as the inlet or detector. Special care should be taken if the column is placed into long transfer lines such as those used for GC/MS.

5.3 Quality Testing

There are several general methods for evaluating the performance of capillary columns. For both packed and capillary columns, perhaps the best method is to monitor one’s own samples. Look for changes in the peak shape and area over time for a known standard. A column which may show poor performance in one application, such as acid analysis (acids are strongly adsorbed on capillary columns in which the deactivation of the silica tubing was poor) may be acceptable for another such as hydrocarbons. Today, most column vendors provide a test chromatogram with every column that provides some indication of the column’s supposed “quality”. These should not be used to compare columns from different vendors, as they are determined under widely varying temperature, flow and injection conditions, which can have dramatic effects on the peak shapes. Figure 4 shows a test chromatogram and data from a typical column vendor.\(^5\,^,\,^6\)

In 1979, K. Grob et al. developed a standard quality test method for capillary columns, with an improved method described in 1981.\(^5\,^,\,^6\) According to Grob, a quality test should contain enough components to provide the needed information, should provide complete information from a single chromatographic run, should be general for all stationary phases, provide some quantitative information and be standardized to allow column comparison. The Grob test is temperature programmed, and evaluates separation efficiency, adsorption of several types of components, and the actual column film thickness.

Separation efficiency can be measured by evaluating the Trennzahl\(^5\,^5\) number (Equation 9):

\[
TZ = \frac{t_{R2} - t_{R1}}{W_{h1} + W_{h2}} - 1
\]

for two homologs. This is essentially the difference between the retention times divided by the sum of peak widths and it expresses roughly the number of peaks that could fit between two adjacent peaks on a chromatogram. A larger Trennzahl number indicates a more efficient column. It is noted that the classical efficiency measure, \(N\), the number of theoretical plates is not easily applied to temperature programmed separations. The Trennzahl number is a measure of the number of peaks of width similar to the homologs that can fit between the homolog peaks.

There are several indications of excessive adsorption or mixed retention mechanisms. These include broadened Gaussian peaks, tailing peaks, reduced peak area and misshapen peaks with long retention. Usually, all of these result in reduced peak height, as compared to a normal Gaussian peak. An abnormally low peak area for a given component usually indicates irreversible adsorption somewhere in the system. Hydrogen bonding is characterized by peak tailing and can be examined using a primary alcohol. An aldehyde can provide an indication of excessive nonhydrogen bonding adsorption, while acidic and basic components can be used to study those interactions. Using these considerations, Grob developed

The Grob test mixtures, for polar and nonpolar columns. The components of these mixtures and their purpose are given in Table 10. The introduction of the Grob test led to many future developments in column deactivation procedures. The specific procedures for using the Grob test mixtures for column evaluation and comparison are given in Grob.\textsuperscript{5,6} The test mixtures used by the column vendors are typically variations of the Grob mixture.

6 RECENT AND FUTURE DEVELOPMENTS

Packed columns currently are used for a fairly stable 20% of GC analyses. Today, they are used for specific applications, such as gas analysis, solvent analysis, process control and education that benefit from the large volume of stationary phase, lower resolution and simple instrumentation. Majors,\textsuperscript{56} who polled both the readership of “LC-GC” magazine and several recognized experts, recently surveyed this. Thus, much of the recent developments in GC stationary phases have been in the improvement of capillary column technology.

With the explosion in capillary GC use that occurred in the 1980s, and the development of quality tests, such as the Grob test mixture, many of the developments have led to better deactivation of the silica tubing and stationary phase materials themselves, improved temperature stability and to a much wider variety of stationary phases, many designed for specific applications, such as United States Environmental Protection Agency (USEPA) approved methods. A recent fundamental survey of GC\textsuperscript{57} shows 76 references in liquid phase developments and 70 articles describing research on solid adsorbents and supports for the period 1994–1997. Much of the research on solid materials has been in the study of surface chemistry and deactivation procedures. Work on liquid phases has been on the development of new phases for specific difficult applications, such as the analysis of light hydrocarbons on capillary columns, and the development of high selectivity for specific compound classes, such as polycyclic aromatic hydrocarbons, substituted benzenes, and chiral separations. Developments in chiral stationary phases, organic polymers and inorganic liquid phases are described here.

6.1 Liquid Phases for Specific Applications

The column vendors have been introducing liquid phases tailored to specific applications and methods for several years. A survey of the major vendors shows liquid phases available for a variety of specialty applications, ranging from specific compendial methods to classes of analytes. Table 11 provides a summary of some applications for which specially formulated liquid phases are available.

6.2 Chiral Stationary Phases

The development of chiral stationary phases for GC has been an active research area in GC for many years. Cyclodextrins and derivatized cyclodextrins are predominantly used for chiral GC applications and have been recently reviewed in the text by Konig.\textsuperscript{58} Due to the

complexity of chiral recognition, many forces are involved in generating separations on cyclodextrin columns. Typically, multiple interactions are required, which may be any or all of the following possibilities. These include hydrogen bonding, van der Waals interactions, size of the inclusion cavity, polar interactions and steric hindrance. Table 12 provides a listing of applications recently described using cyclodextrin columns.

6.3 Organic Polymer Stationary Phases

As described above, most modern GC liquid phases are composed of organic polymers that are coated into capillaries or onto solid supports. Most of the recent research and development of new polymeric substances can be divided into several areas: classification of currently available materials, liquid crystals, crown ethers, substituted silicones and chemically bonded cyclic organo-siloxanes (silica gels). Research on the specific interactions that determine retention on GC liquid phases continues today, with Santiuste and Takacs describing the interaction capacity of 26 common liquid phases. Rohrschneider recently reviewed work in the general area of phase constants for liquid phase characterization. Several workers have employed liquid crystals as GC stationary phases. Liquid crystals have recently been employed for the separation of hydrocarbons, dioxins, phthalic acids and polycyclic aromatic hydrocarbons. Liquid crystals show promise for the separation of positional isomers of both aliphatic and aromatic compounds. Crown ethers have been bonded to polysiloxane liquid phases to provide special selectivity for short chain alcohols, ethyl esters of carboxylic acids and substituted benzene and phenol isomers. Sol–gel technology has recently been used to make stationary phases for capillary columns with very high surface area and thermal stability, improving both capacity and ruggedness.

### 7 CONCLUSIONS

The liquid phase is the heart of the GC separation system. It is here where all separation occurs. Development of new liquid phase technologies began along with the invention of GC and continues to be active. The renaissance in GC development that began with the introduction of fused silica capillary columns in 1979 also strongly affected stationary phase development. Today’s capillary columns are relatively inexpensive, rugged, reproducible, inert and are available in a large variety of dimensions and liquid phases. In the future, new liquid phases that are more inert, have lower bleed, or address specific chemistries will continue to be developed. Stationary phase development continues to be a very active area of GC research and development.

### ACKNOWLEDGMENTS

This article is respectfully dedicated to the memory of Professor Mathew Petersheim (1954–1998), friend, mentor and chair of the Seton Hall University Department of Chemistry from 1994–1996, who was taken from us far too soon.

### LIST OF SYMBOLS

- $\alpha$: selectivity
- $\beta$: column phase ratio
- $d_p$: packing particle diameter
- $d_f$: stationary phase film thickness
- $D_M$: diffusion coefficient of an analyte molecule in the mobile phase
- $D_S$: diffusion coefficient of an analyte in the stationary phase
- $\Delta G^\circ$: standard free energy change
- $\gamma$: tortuosity factor in the van Deemter Equation – related to the column packing
- $H$: height equivalent to a theoretical plate
- $K$: partition coefficient
- $k$: retention factor
- $\lambda$: packing factor – a constant in the van Deemter Equation related to the packing efficiency of the particles
- $\mu$: average linear gas velocity
- $N$: number of theoretical plates
- $N$: carbon number of the normal alkane eluting immediately before an analyte
- $N + 1$: carbon number of the normal alkane eluting immediately after an analyte

Two-dimensional gas chromatography (2-D GC) is a logical extension of gas chromatography (GC) carried out on a single column. It provides physical resolution of components which are difficult to analyze by other means. Two different arrangements are possible in 2-D GC. In the conventional mode, effluent fractions from the primary column are switched onto a secondary column of different polarity. In this arrangement, the sample inevitably comes into contact with the metal of the valve body. The other design is based on fluidic switching by application of a difference in pressure in the interface between the columns. This technology, generally referred to as Deans switching, can avoid metals in the sample flow path but it is technically more difficult than valve-based technologies.

Comprehensive 2-D GC involves a focusing step. The effluent from the primary column is periodically injected into a high speed column in the form of narrow chemical pulses. The separation on the secondary column must be complete (or nearly complete) before the next pulse can be injected. The secondary column is polar, i.e. substances that have similar boiling points but differ in polarity can be resolved in the second dimension. The separations process is continuous and resembles data acquisition in routine gas chromatography/mass spectrometry (GC/MS). One of the true advantages of comprehensive 2-D GC is that the separations mechanisms on both columns can be decoupled, leading to true orthogonality. Components with similar properties fall into clearly defined data spaces. The chromatograms show a measure of order which is useful in substance identification and group type analysis.

Comprehensive 2-D GC is still in its infancy. There is much room for improvements, including in the data acquisition/display area. Conventional 2-D GC, however, is mature. Because of the complexity of 2-D GC instrumentation, selective detection, i.e. GC/MS, is usually preferred where it is applicable. Many applications based on 2-D GC have been published. The analysis of flavors/fragrances, petrochemicals and persistent organohalohogens in the environment by 2-D GC offers distinctive advantages over competing technologies.

1 INTRODUCTION AND HISTORICAL PERSPECTIVE

GC is undoubtedly the most widely used technique for the separation of volatile components. It is amenable to the analysis of a wide range of organic and inorganic materials. Some of the strongest aspects of GC come from its operational characteristics. It is relatively easy and inexpensive to achieve high separation power and short turnaround times. The wide array of excellent general and specific detectors available for GC is perhaps one of its biggest attractions. There is no other instrument in chromatography that can offer this level of performance. GC occupies an important position in
the array of separation techniques. Although it is not the oldest form of chromatography, it was the first one to mature as an instrumental technique. Relatively sophisticated instrumentation based on packed column technology and flame ionization detection or electron capture detection became commercially available in the late 1950s and early 1960s. The separation power and versatility of capillary column GC was demonstrated early on. Efficient metal capillary columns with apolar stationary phases were relatively easy to produce but problems due to active surfaces could not easily be conquered.\(^\text{(1)}\) The introduction of glass as a column material opened an avenue to overcome this major hurdle.\(^\text{(2)}\) Glass drawing machines became commercially available and aided in the development of this column type. Many recipes were offered for the production of truly inert surfaces and stationary phase coating techniques were perfected.\(^\text{(3)}\) Immobilized stationary phases, introduced in the early 1970s, were another major development.

Many scientists have contributed to the advancement of capillary column technology during these years. History records many individual inventions and advancements. No individual was as influential in the overall development of glass capillary column technology as Grob.\(^\text{(4)}\) One might have assumed that chromatographers would jump at this new development and substitute packed column applications demanding high resolving power with capillary column based methodology. Unfortunately, little progress was made in this respect. Glass proved to be too difficult to handle on a routine basis and capillary column dedicated instruments were not built because of patent infringement issues. The situation again changed dramatically in 1979 when a scientist working for the Hewlett Packard Company invented a thermal modulator as a sample introduction device. Comprehensive 2-D GC is less than 10 years old.\(^\text{(5)}\) Flexible fused silica capillary columns quickly replaced glass capillary column technology. This column type was not only easier to handle from a practical perspective but a wide variety of commercial columns were introduced onto the market shortly after the basic patent expired. Capillary column GC finally took off. It is not surprising that many scientists pushed the exploration of the principles of GC to its limits. The introduction of an entirely new family of affordable spectrometers as on-line detectors made a major impact. The practical limits of GC as a tool and as a technique were eventually fall by the wayside.\(^\text{(6)}\)

2-D GC is one of the most effective techniques to deal with multicomponent samples, especially those consisting of substances having a wide range of polarities. The principle is simple: components that experience similar retention characteristics on one particular stationary phase are subjected to an additional separation step on a second column of different selectivity. Two components of approximately the same boiling point which elute on an apolar phase as a single peak may have different functional groups. Differences in polarity, polarizability, etc., can then be exploited. This process can be carried out off-line but this technology is very difficult for trace components. On-line techniques rely on some type of column switching hardware that allows the transfer of an effluent fraction between the columns. This type of manipulation, generally referred to as heartcutting, GC/GC, or 2-D GC, has been used since the mid-1950s, primarily in process control. Simmons and Snyder\(^\text{(7)}\) are credited with the first use of 2-D GC in general analysis. In principle it is possible to resolve component(s) from a mixture as long as a set of stationary phases is available that differentiates between the target compound(s) and its interferences. Full characterization of a complex sample requires the transfer of a large number of individual cuts. The process becomes laborious and time-consuming. In practice, there are other hurdles to overcome as well. As long as only a single heartcut is being made, it is possible to correlate a secondary chromatogram to a transfer from the primary column. This advantage is lost when multiple heartcuts are made in the course of a single run. Since stationary phases act independently, components from individual transfers tend to mingle and can thus no longer be correlated.

A technical solution to carry out multiheartcut 2-D GC has been developed. Narrow slices of effluent are periodically injected from a primary column into a short, high-speed secondary column. Components which are not resolved in the first dimension undergo a second separation step. The process is analogous to routine GC/MS and is known as comprehensive 2-D GC. In both processes, the entire sample is sliced into narrow packets for further examination. The practical implementation of comprehensive 2-D GC is the brainchild of Phillips who invented a thermal modulator as a sample introduction device. Comprehensive 2-D GC is less than 10 years old.\(^\text{(8)}\) As with any new technology, there are still many obstacles to be overcome. The technical side is moving along nicely. New ground had to be broken in several areas, notably in data acquisition and display. The situation can be compared to the early days of GC/MS when analog to digital interfaces and computers were slow and of limited capacity. Looking at the steady progress in GC/MS, one has to be optimistic that current stumbling blocks will eventually fall by the wayside.

The inventors and proponents of comprehensive 2-D GC have not done a very good job of “selling” their invention. Many chromatographers who are quite knowledgeable remain skeptical because the fundamental principles, technical approaches and strengths/weaknesses of
MULTIDIMENSIONAL GAS CHROMATOGRAPHY

this new tool have not been adequately explained. There is also a lack of general applications. At present only one small firm\(^9\) has secured the rights to exploit the patents issued for the basic design\(^{9,10}\). No more than around a dozen laboratories in the world are actively pursuing research in a major way in this area.

2-D GC is a multifaceted technique. Its major use is in the physical separation of multicomponent mixtures but there are other areas of application as well. The preparative scale isolation of trace components in a complex mixture is an example. Hardware differs for conventional heartcutting-type operations and comprehensive 2-D GC differs significantly. It is described in separate paragraphs.

2 PEAK CAPACITY AND OVERLAP IN GAS CHROMATOGRAPHY

Two-dimensional separation procedures become especially important when complex samples consisting of hundreds of components must be analyzed. Resolution in GC depends on several factors. For isothermal conditions, Equation (1) applies:

\[
R_s = \frac{1}{4} \left( \frac{\alpha - 1}{\alpha} \right) \left( \frac{k'}{k' + 1} \right) \sqrt{\frac{L}{H}} \tag{1}
\]

where \(R_s\) is resolution, \(\alpha\) selectivity, \(k'\) solute retention factor, \(L\) column length, and \(H\) theoretical plate height. Since the number of theoretical plates is proportional to column length (Equation 2)

\[
N = \frac{L}{H} \tag{2}
\]

where \(N\) is the number of theoretical plates, resolution varies with the square root of column length. Retention, and thus time of analysis, is however directly proportional to column length. In practice, resolution also depends on other factors such as the relative magnitude of the peaks being resolved. Merged peaks of approximately equal height can easily be recognized and quantitated with good accuracy at less than unit resolution. As peak ratios continue to deviate, merged peaks become less distinctive. In practice, it is not uncommon to quantitate adjacent components in a chromatogram that differ in concentration by several orders of magnitude.

Even though Equations (1) and (2) are useful in describing fundamental relationships in GC, they are very limited in practice. The vast majority of GC separations are carried out under temperature programmed conditions. Unfortunately, the effects of temperature programming on resolution are complex and difficult to describe. An alternative way to evaluate the separation power of a column under both isothermal and temperature programmed conditions is the use of the peak capacity concept. Peak capacity is defined as the maximum number of component peaks that can be packed side by side into the available separation space at a given resolution\(^{11}\). The frequency of component overlap is thus a function of peak capacity. For isothermal runs, peak capacity \(n_c\) can be related to the number \(N\) of theoretical plates as shown in Equation (3)\(^{10}\)

\[
n_c = \theta N^{1/2} \tag{3}
\]

where \(n_c\) is peak capacity, and \(\theta\) is a variable that depends on retention time range. The determination of peak capacity under conditions of temperature programming is complex\(^{12}\). In conventional capillary column GC, typical peak capacity values are in the range of a few hundred. It would appear that peak capacities of this magnitude would be adequate for all but the most complex samples. Unfortunately, this is not the case. Davis and Giddings\(^{13}\) developed a concept based on the random distribution of component peaks in chromatographic separation space. The mathematical treatment which is based on Poisson statistics is now commonly referred to as the statistical model of overlap (SMO) theory. It has been refined and expanded for the last 20 years by Davis\(^{14}\), a former Giddings student, and his group. Alternative concepts for the evaluation of statistical peak overlap have also been offered\(^{15,16}\). Regardless of the model used, the relationships are complex and the findings are not easily applicable in practice. Simple calculations show, however, that single column systems are not capable of producing separation numbers which are adequate even for samples of only moderate complexity.

SMO theory can be used to predict resolution as a function of several variables. The number of peaks \(p\) observed in a chromatogram and the expected component number \(m\) in a sample are related to column peak capacity \(n_c\) as shown in Equation (4)

\[
p = m e^{-m/n_c} = m e^{-\alpha} \tag{4}
\]

where \(\alpha\) is the saturation factor. In the special case where the expected number of components is equal to the peak capacity of the column at hand, the function reaches a maximum. With random spacing, only 37% of the peaks can theoretically be resolved. Resolution becomes an exponential function of peak capacity, as shown in Equation (5)

\[
\left( \frac{p}{n_c} \right)_{\text{max}} = e^{-1} = 0.3679 \tag{5}
\]

In practical chromatography, the results are even worse since factors such as peak distortion, peaks differing in magnitude, instrument noise and similar disturbances
have not been considered in this model. The number of single component peaks \( s \), shown in Equation (6), is smaller than \( p_i \):\(^{(14)}\)

\[
s = me^{-2m/n_c} = me^{-2a}
\]

(6)

The number of peaks representing single components cannot exceed 18% of the available peak capacity \( n_c \). The ratio \( s/m \) represents the fraction of all components isolated as single component peaks. It can be expressed as probability \( P_1 \), as shown in Equation (7):

\[
P_1 = \frac{s}{m} = e^{-2a}
\]

(7)

As expected, the occurrence of single component peaks is linked to saturation.

Some examples can illustrate the consequences of statistical component overlap and point toward potential remedies. Consider a sample consisting of 50 components which needs to be analyzed on a column having a peak capacity \( n_c \) of 100. It would appear that most components should be adequately resolved, since twice the necessary peak capacity is available. Only 18 substances or 36% of the sample will however be represented as single component peaks.\(^{(13)}\) This is a clear disappointment. Decreasing the level of saturation improves the chance of obtaining single component peaks but the gains are painfully slow. At \( \alpha = 0.5 \) and \( \alpha = 0.25 \), \( P_1 \) increases to 37% and 61%, respectively. To elevate \( P_1 \) to 82%, saturation \( \alpha \) must be lowered to 0.1, i.e. a 10-fold excess of peak capacity must be available. Equations (4) and (7) show that the 100-component sample requires a column peak capacity \( n_c \) of 288 for a relatively modest probability \( P_1 \) of 50%. Under favorable circumstances, this separation can be achieved on a column producing 100000 theoretical plates. To increase the probability to 90% and 99%, respectively, columns of 4000000 and 5000000 theoretical plates are required. This type of performance is clearly outside the range of most GC instruments. The current limit of single column GC is around 4000000 theoretical plates, corresponding to a peak capacity \( n_c \) of approximately 1000.\(^{(17)}\) Gasoline, a sample of moderate complexity, was analyzed on such a system. The chromatogram produced 970 distinguishable signals, mostly in the form of merged peaks. The results from this analysis are impressive but it took 15 h to complete the separation.

The achievement of high efficiency carries another price tag. Since plate height \( H \) is approximately inversely proportional to the inverse of column diameter, small bore columns have to be used. Columns with small internal diameter not only produce a high pressure drop but the amount of stationary phase available also becomes a limiting factor.\(^{(18)}\) Columns of 50–100 \( \mu \)m internal diameter have low sample capacity and are difficult to operate.\(^{(19)}\) Recycle chromatography is an alternative to overcome both limitations. This technique is based on the use of two relatively short conventional capillary columns connected via a low dead volume valve. The effluent fraction which requires further resolution is alternatively routed through each of the columns by turning the valve at the appropriate time. A recycle unit consisting of two 20-m segments produced over 2 000 000 theoretical plates for a run consisting of 20 cycles.\(^{(20)}\) Large peak capacities can easily be obtained. The resolution of isomer pairs such as pristine and phytane which requires very high efficiencies on any stationary phase can be accomplished. Recycle operations are quite amenable to 2-D GC because they are already based on the use of valves. There is a problem however with the timing of valve switching. A very low dead volume in-line detector is necessary or some of the effluent has to be diverted to an off-line detector. The prospects of recycle GC are exciting but these problems must first be overcome to make it truly competitive.\(^{(21)}\)

2-D GC can provide an alternative to single column GC when highly efficient systems are required. There are two conditions that must be fulfilled: (1) the components must be subjected to two separation steps (mechanisms); and (2) once separation has been achieved in any single step, the substances must remain separated.\(^{(22)}\) The power of 2-D GC comes from the use of complementary stationary phase selectivities and the utilization of the “empty space” in the second column. Figure 1 shows a basic diagram of the separation concept in a coupled column system. It is obvious that narrow heartcuts reduce the chances of coincidental overlap in the second column. From a practical point of view, one needs to consider additional factors.

- Components which have undergone peak broadening in the primary column continue to do so in the secondary column. Final peak widths may become unacceptable.

![Figure 1](image-url)

Figure 1 Schematic diagram of idealized 2-D GC showing a single heartcut.
Peaks that are already partially separated may merge in the secondary column due to "a mixed phase mechanism".

It may be difficult to correlate the retention times of components on both columns unless one can keep track of their relative movements.

The installation of an intermediate trap between the columns is a way to overcome some of the hurdles. Solutes can be refocused and reintroduced as narrow pulses. In this manner, relatively broad cuts can be taken. As the width of the cut is widened, an increasing number of substances is introduced and a point of diminishing return is eventually reached. The other extreme is the transfer of effluent on the timescale of the width of a single peak. Narrow heartcuts are likely to produce only a few components in secondary chromatograms. There is an obvious balance between the number of transfers, complexity of secondary chromatograms, and time requirements.

The major use of heartcutting in 2-D GC is the physical separation of a few trace target compounds in the presence of major interferences. The complete two-dimensional characterization of a sample requires a different approach. Figure 2 shows an arrangement where adjacent heartcuts are performed within the same run. The maximum peak capacity \( n_{c\text{max}} \) of such a system is approximately given by Equation (8):

\[
n_{c\text{max}} = \bar{n}_c \times \text{number of columns} \quad (8)
\]

where \( \bar{n}_c \) is the average peak capacity of the columns used in the system. Two independent secondary columns allow the separate development of individual heartcuts. Components eluting at the interface between the individual transfers will be found in both secondary chromatograms. All other substances will appear in only one of the chromatograms. The components which have been resolved on the first column thus remain separated. It is obvious that the complete characterization of a sample in an assembly of multiple secondary columns is not practical. As an alternative, an arrangement using multiple parallel traps can be used.\(^{23,24}\) Effluent from the primary column is essentially stored in these traps. This approach differs from the conventional heartcut-type operation indicated in Figure 1. The contents of each trap can be injected into the secondary column, one at a time. The ambiguity introduced by multiple heartcutting is thus eliminated. There are some practical problems, as expected. The apparatus is complicated and the adsorbents used in the traps may have a tendency to interact with some of the more delicate sample components. The use of recently introduced polysiloxane-based trapping materials can overcome activity problems.\(^{25}\)

The most effective way to improve the total peak capacity of a system is the addition of a large number of secondary columns. Figure 3 shows the equivalent of a two-dimensional separation in planar chromatography. The hardware giving access to this type of dispersion in GC is actually quite simple, at least in principle. The effluent is focused as it emerges from the end of the primary column. It is then periodically injected as a series of sharp pulses into a single secondary column. Elution time from the secondary column is synchronized to the frequency of injection from the primary column, i.e. the last component must have left the secondary column before the next pulse is injected. This type of operation is referred to as comprehensive 2-D GC because the entire sample is processed in a comprehensive manner.

\textsuperscript{a} Symbols (++, +, +/-, – and ––) indicate suitability.

The maximum peak capacity of such a system can be approximated by Equation (9):

\[ n_{c(max)} = n_{c(1)} \times n_{c(2)} \]

where \( n_{c(1)} \) and \( n_{c(2)} \) are the peak capacities of the primary and secondary columns, respectively.\textsuperscript{(26)} The term GC \( \times \) GC which is used interchangeably with the term comprehensive 2-D GC emphasizes the multiplicative nature of individual column peak capacities in the combined system. Although there are some restrictions on the optimal use of this technology, it is clearly the only practical route toward the achievement of very high peak capacities. At the present time, peak capacities \( n_c \) approaching 54 000 have already been demonstrated.\textsuperscript{(27)}

Instrumentation and methodologies of conventional 2-D GC and comprehensive 2-D GC differ in many aspects. There are distinct advantages and disadvantages to each type. It is difficult to make generalizations because the suitability of a particular type of 2-D GC depends on details of the particular instrument design and on the problem at hand. Table 1 is a general overview of advantages and disadvantages of the basic instrument types available.\textsuperscript{(28)} Aspects of conventional 2-D GC and comprehensive 2-D GC are presented separately.

3 CONVENTIONAL TWO-DIMENSIONAL GAS CHROMATOGRAPHY

3.1 Instrumentation and Procedures

2-D GC instrumentation consists of an arrangement of two columns where one of the columns acts as inlet for the other one. Functional instruments require a great deal of attention to the interaction between sample components and surfaces and to unswept volumes in interfaces. Contact of sample components with unsuitable surfaces has the potential of causing undesirable reactions or tailing due to adsorption. Excessive transit times are a source for experimental dilution and band broadening. Interestingly, little information has appeared in the recent literature on new developments and refinements of 2-D GC hardware. Most of the developments in 2-D GC date back to the 1970s and 1980s. This is in stark contrast to many other areas of GC where improved technology has driven instrument design to new heights.

The introduction of low cost spectrometric detectors, in particular the mass spectrometer, has diverted much interest away from 2-D GC. The emergence of routine MS in conjunction with GC is the main reason why 2-D GC has not flourished. These techniques are in competition with each other. Table 2 summarizes trends in both disciplines.

Benchtop-type GC/MS is relatively inexpensive, versatile and has a user interface conducive to the production of large volumes of data. In contrast, 2-D GC requires fine-tuning and is relatively difficult to carry out. In many
situations, mass spectra of target compounds are sufficiently different from the interfering background to permit characterization and quantitation with little or no chromatography. Mass spectral selectivity is often substituted for chromatographic resolution. Unfortunately, there are many pitfalls to this approach. A great deal of unreliable data may be generated from the inappropriate use of MS. There are many situations where the physical separation of target compounds is the only viable option. MS can generate highly reproducible data which may suffer from the same interferences. High precision is often taken as an indicator for accuracy. Interferences in MS are very common because related substances produce common ions. Strict quality control measures must be put in place to safeguard against poor data quality.

Conventional 2-D GC instrumentation offers a wide variety of options. In the most simple case, the columns are connected via a microvalve and are placed in a single oven. Complex instruments feature sophisticated pressure balanced pneumatic switches under conditions of mass flow control. This principle is often referred to as a Deans switch, after its original proponent. A secondary inlet for the injection of calibration standards into the second column and a monitor detector between the two columns are useful, almost necessary, additions. Other features include dual ovens, a computer controlled interface responding to events in real time, an intermediate trap and a sophisticated selective detector, such as a mass spectrometer, infrared spectrometer, or atomic emission spectrometer. In special cases where the on-column enrichment of trace components is required, a parallel trap accessory may be a part of the instrument.

Figure 4 shows the design of such an instrument. This particular design is geared toward the on-line evaluation of flavors and fragrances and features two Deans-type switches. This instrument can be equipped with a variety of detectors, including a sophisticated isotope ratio mass spectrometer. Isotope ratio MS is an important tool to uncover adulteration in the food industry and study details of biosynthesis and metabolism. Valve-based instruments can also be quite sophisticated. Figure 5 shows the design of such an instrument. Only one of the five valves actually comes into contact with the sample. The other units are used to carefully balance pressures and turn on/off the flows in the rest of the instrument. Vacuum can also be used to switch effluent between columns. The effluent is virtually sucked into an interface, as it emerges from the primary column.

Contact of the sample with surfaces other than well deactivated glass or fused silica is of much concern. It is obvious that valve-based systems must contain metal that may cause problems with labile compounds. Instruments equipped with Deans-type switches can totally avoid metals in the effluent flow path. Arrangements based on fused silica column technology permit the use of friction-type connectors, tees and crosses which are made of glass and can thus be well deactivated. Metal, in particular stainless steel, has perhaps an unjustified bad reputation as a poor chromatographic surface. Instruments equipped with both valves and Deans-type switches have been compared for potential artifacts. The results are inconclusive. Oxygenated compounds, in particular free acids, anhydrides, and aldehydes, are usually good indicators of residual activity.
appears that noble metals such as Pt/Ir may not be as inert as many users imagine. There is at least one report on the tautomerization of α-ketols on a commercial 2-D GC instrument that uses a small piece of Pt/Ir in its interface.\(^\text{(42)}\) Significant advances have been made in the deactivation of metal surfaces within the last 5 years. Columns are now available that can compete with fused silica in every aspect, including inertness. The controversies point out that each situation should be evaluated on a case-by-case basis.

Compared to other developments in GC, relatively little progress has been made in the advancement of 2-D GC instrumentation over the last 20 years. Commercial aspects have also been rather subdued. Most instrument manufacturers seem to be willing to modify or adapt instruments for 2-D GC. A dedicated instrument however is available from only one source, the Siemens Co. This instrument is based on a Deans switch and has a dual oven configuration. The design is largely based on the work of Schomburg and his group who have pioneered many developments in the design of 2-D GC instrumentation.\(^\text{(43–45)}\) Figure 4 shows some details of the heart of this instrument, referred to as a live switch. There are several suppliers and specialty companies that

Figure 5 Pneumatic layout of a valve-based double-oven two-dimensional system. Note that the instruments can be operated separately or as a single unit. P, pressure controller; R, restrictor or needle valve; NO and NC, normally open and normally closed position, respectively. Only valve 1 (heated) is in the effluent flow path. (Reproduced by permission from Mondello et al.\(^\text{(33)}\))
provide components for the conversion of conventional instruments to 2-D GC use. The DANI, SGE, AC Controls and Gerstel companies provide accessories and instrument modification based on the Deans principle. These firms are headquartered in Italy, Australia, Holland and Germany but have outlets in the USA and many other countries. The switching components include external computer controlled solenoid valves. Mass flow control is a preferred way to ensure the stability of switching under conditions of temperature programming.\(^{46}\) The timing of effluent switching can be a very critical issue. It is sometimes important to divert a single peak, such as an unresolved pair of enantiomers, into a secondary column. One of the most elegant ways to ensure precise cutting is to use an internal standard. This principle has been implemented. The system determines the accurate position of a cut by calculation of retention indices and makes adjustments to compensate for changes.\(^{47}\) The pressure–flow relationships in Deans-type switches are now well understood.\(^{48}\)

The use of an intermediate trap between the columns raises challenges but also provides for additional flexibility. A trap must be capable of the retention of the target analyte and, more importantly, allow rapid reinjection. A variety of designs have been offered.\(^{49,50}\) Details of the performance of individual components and instrumentation are beyond the scope of this discussion. The reader is referred to the original literature. Several reviews are available on the subject.\(^{44,51–56}\) There is also extensive coverage of 2-D GC in general textbooks.\(^{57,58}\) It is interesting to note that only a single review has appeared within the last 8 years.\(^{59}\)

### 3.2 Practical Aspects

Even though the major use of 2-D GC is for the resolution of target components in complex mixtures, it is also useful in other areas. A general lack of sample capacity is a major problem associated with the use of narrow bore thin film columns. Multiple injections can be used to build up the targeted trace component(s) to a level where adequate detection or preparative scale isolation is feasible. Instruments with intermediate traps or parallel traps are particularly suitable for this purpose.\(^{60,61}\) Analysis time is another major issue. Column flow can be reversed after the heartcut has taken place. Backflushing techniques can be incorporated into heartcut operations. This approach saves much time in routine analysis.

The complete characterization of a complex sample is perhaps the most difficult of all situations. The analysis of tobacco smoke is the classical example of a truly complex sample. Tobacco smoke condensate consists of thousands of substances at the parts per million level and above. The substances appear in a wide range of concentrations, are often multifunctional and may have both acidic and basic properties. Figure 6(a) shows a chromatogram of a tobacco essential oil on the first column of a two-dimensional system.\(^{62}\) The resolving power of the column is modest but it is apparent that the separation, especially of minor components, would still be inadequate on a more efficient column. Figure 6(b) presents chromatograms derived from two of the heartcuts. Approximately 1500 peaks were observed and 300 were identified using mass spectra and retention indices. It is likely that secondary chromatograms still contain unresolved components. This is a situation where another separation step may be necessary.

### 3.3 Selected Applications

2-D GC applications have been described for many analytical problems amenable to GC. There are three distinctive areas where 2-D GC has really made an impact and is thus in routine use. These are in certain aspects of petroleum chemistry, the analysis of persistent chlorinated substances in the environment and the food/fragrance industry. The classification of crude oils and petroleum-based distillates is the oldest and most traditional application of conventional 2-D GC.

Petroleum contains mainly hydrocarbons and heteroatom compounds. Both groups are of interest. Heteroatom compounds include the elements sulfur, nitrogen and oxygen. Substances of this type are usually undesirable because they are potent catalyst poisons and potential air pollutants. Petroleum-type samples are often subjected to group specific reactions or are selectively determined by spectroscopic methods. The American Society for Testing and Materials (ASTM) has issued a large number of individual methods. Hydrocarbon analysis makes use of many disciplines of chemistry. Hyphenated techniques such as liquid chromatography/gas chromatography (LC/GC) and GC/MS are particularly useful. One of the most common types of analysis involves the speciation and quantitation of paraffins, isoparaffins, olefins, naphthenes and aromatics, abbreviated as PIONA. The routine determination of petroleum products in terms of these substance classes is very important. As an example, high olefin content is undesirable because these compounds are unstable. The refinery engineer requires reliable data to optimize the blending of process streams and for many other critical operations.

Hydrocarbons in petroleum are extremely complex. There are some \(4 \times 10^7\) potential paraffin isomers in the \(C_{10}\) to \(C_{25}\) carbon range alone.\(^{63}\) PIONA analysis by 2-D GC is carried out in instruments that consist of a series of valves, traps, absorbers and reactors. Effluent is switched back and forth among as many as five columns. Each column is optimized to deal with
a particular range of compounds. A dedicated PIONA analyzer was originally introduced in 1971 when packed columns were widely used.\textsuperscript{(64)} The basic instrument has undergone considerable refinement over the years but its basic design has changed little.\textsuperscript{(65,66)} With the introduction of reliable capillary columns, packed columns are being phased out.\textsuperscript{(67–72)} MS is increasingly used as an additional tool. Figure 7 shows the outcome of a typical two-dimensional separation.\textsuperscript{(73)} A mass spectrometer was able to deconvolute overlapping peaks. The analysis of highly volatile materials, which has been traditionally done by gas solid chromatography\textsuperscript{(74)} on packed columns, can now easily be conducted on the new generation of porous layer open tubular (PLOT) type capillary columns.\textsuperscript{(75,76)}

2-D GC is also very useful in geochemistry and oil exploration.\textsuperscript{(76)} The analysis of alkynaphthalenes in crude oil is a good example to illustrate the value of 2-D GC as an indispensable tool. Alkynaphthalenes are important indicators of geochemical parameters such as the thermal history (maturity) of sedimentary organic matter.\textsuperscript{(77)} The ratio of alkynaphthalene isomers and other fused aromatic hydrocarbons is an important indicator. These
Figure 7 Chromatograms of a petroleum distillate (monoaromatic hydrocarbons). Chromatograms A (column 100 m × 0.25 mm × 1.2 μm, 5% phenyl 95% methyl polysiloxane) and B (column 25 m × 0.32 mm × 1.0 μm, free fatty acid phase) correspond to primary and secondary separations respectively. (Reproduced by permission from Hendrickx and Ramaekers.\textsuperscript{[73]})
substances cannot be determined by MS because the mass spectra of the isomers are virtually identical. Only 2-D GC can achieve complete resolution.\textsuperscript{(78,79)} Recently, there have been some exciting developments in comprehensive 2-D GC where some peak overlap can be accommodated without the use of valves or other switching devices. Details will be provided in a later paragraph.

The second area where 2-D GC has made a major impact is in the analysis of persistent organohalogens in the environment. The major culprits are chlorinated biphenyls, toxaphenes, dioxins, furans and some pesticides. In many cases, one has to deal with mixtures of isomers in complex matrices. The compounds are usually present at very low levels and detection by selective detectors, in particular the electron capture detector, is necessary. Analysis requires speciation, i.e. the composition of individual isomers must be determined because toxicity and biodegradation between congeners may vary by orders of magnitude. Polychlorinated biphenyls (PCBs) may contain up to 209 distinctive chlorine substituted biphenyl structures.\textsuperscript{(80)} Much effort has been devoted to finding a selective stationary phase capable of resolving the majority of the 150 congeners that may be present in significant quantities.\textsuperscript{(81–83)} A perfect phase has not been found. The sample is simply too complex. 2-D GC, however, can solve the problem.\textsuperscript{(84,85)}

The analysis of PCBs which display axial chirality in their nonplanar conformations is an interesting and challenging problem. It is obvious that the atropisomers must be resolved on a stationary phase with chiral selectivity. Modified cyclodextrins are particularly useful for this purpose.\textsuperscript{(86)} The typical two-dimensional gas chromatograph contains an apolar primary column and a chiral secondary column. Data from environmental

![Figure 8](image)

**Figure 8** Influence of width of heartcut on the number of compounds isolated from a mixture of polychlorinated dioxins and furans. (Reproduced by permission from Schomburg et al.\textsuperscript{(90)})
samples show that there are indeed differences in the biodegradation of different atropisomers.\textsuperscript{87, 88} The analysis of toxaphenes which are composed of borane and camphene derivatives provides similar challenges. 2-D GC is amenable to the determination of the various isomers.\textsuperscript{89} The determination of chlorinated dioxins and benzofurans is perhaps one of the best known applications of 2-D GC. These classes include some of the most toxic substances ever recorded. Figure 8 shows an application from Schomburg’s laboratory dating to the mid-1980s.\textsuperscript{90} It is apparent that the width of the window selected for heartcutting has a major influence on the outcome of the analysis. The example shows that the heartcut containing the substance of interest, the 2,3,4,8-congener, must be chosen with precision. Photodegradation studies also rely on high resolution because the fate of individual congeners must be followed to establish correlations between structure and photodegradation rates.\textsuperscript{91} High-resolution MS and multisector MS are useful alternatives for dioxin analysis but this technology comes at considerable cost.\textsuperscript{92, 93}

Pesticide analysis is another important area of analysis where 2-D GC is useful. The trade in foods between different countries requires the routine monitoring of samples for any of the 300 compounds that have been introduced. Most pesticides contain a combination of halogen, nitrogen, phosphorus and sulfur and are thus amenable to selective detection. A combination of electron capture detector, flame photometric detector and nitrogen/phosphorus detector is often used. Identification is usually based on a combination of retention time and detector response ratios.\textsuperscript{94} MS is also useful.\textsuperscript{95} In critical cases, 2-D GC has to be used in conjunction with selective detectors.\textsuperscript{96}

The third area where 2-D GC is widely used is in the analysis of flavors and fragrances. The human nose is a very selective detector that requires a pure substance for organoleptic evaluation. Odor thresholds vary by orders of magnitude. Enrichment may thus become necessary.\textsuperscript{97–99} The analysis of essential oils is of considerable interest.\textsuperscript{100–102} In practice it is often also necessary to determine the source of “off-flavors” in a product that has been rejected by the consumer. Quite often, the substance(s) responsible for the objectionable flavor or taste is present in minute concentration(s) and 2-D GC is the only workable solution.\textsuperscript{90} Figure 9 presents an application of this type.\textsuperscript{104} The defective coffee sample produced a 10-fold increase of one component. It should be noted that the primary column was intentionally overloaded to provide an adequate amount for mass spectral identification.

Many compounds produced in nature are optically active. The determination of enantiomeric ratios is important.\textsuperscript{104–107} It is routinely carried out for a variety of fruits and other natural products.\textsuperscript{108–110} Enantioselective 2-D GC is a powerful tool to detect adulteration in foods.\textsuperscript{111} Nature usually produces one of the enantiomers in excess whereas synthetic products are racemates. The origin specific analysis of flavors is also possible. Under conditions of identical metabolic pathways, isotope ratios should be indicators of a specific environment. The measurement of carbon-12 to carbon-13 ratios is particularly useful. Isotope ratios provide conclusive evidence. 2-D GC can be combined with on-line isotope MS in the authentication of foods.\textsuperscript{31, 112, 113} The measurement of isotopes requires high precision. Data from isotope measurements are increasingly integrated in many areas where fingerprint-type comparisons are necessary.\textsuperscript{114} Regardless of the problem at hand, analysis

![Figure 9](image-url)
of enantiomers requires the use of standards or retention time libraries because mass spectra of enantiomers are identical.

A considerable body of data has been assembled in the three areas for which some examples have been presented. Much of the information is published in specialty journals. The reader may want to contact the appropriate original sources for additional details.

4 COMPREHENSIVE TWO-DIMENSIONAL GAS CHROMATOGRAPHY

Conventional 2-D GC has inherent limitations. Single heartcuts yield unambiguous results. Narrow heartcuts obviously provide the highest resolution potential because the transferred effluent is likely to contain only a few components. As the window of the heartbeat widens, the probability of overlap in the second dimension also increases. The basic tradeoffs have been demonstrated in Figure 8. Addition of an intermediate trap does not fundamentally change the situation. The primary advantage of an intermediate trap is its ability to reverse the effects of band broadening from the first column. To save time, users often cut multiple effluent fractions into the intermediate trap. This practice is usually acceptable if the different heartcuts are far apart. The chances of the mixing of compounds from different heartcuts on the secondary column depends primarily on the spacing of the cuts and the difference in stationary phase polarities. The chance of interferences is minimal if only widely distanced heartcuts are taken. Accidental overlap from adjacent fractions can be eliminated by diversion of the effluent into a series of parallel traps or into separate secondary columns. Both of these operational modes have problems. Multitrap arrangements require much time because analysis is sequential. Elution from the secondary column must be complete before the contents of the next trap are introduced. Parallel columns do not have this time penalty but the cost and complexity of the system increase.

The complete characterization of a wide boiling range sample can be accomplished by comprehensive 2-D GC. The term “comprehensive” implies that the entire sample is subjected to periodic heartcuts in a fashion analogous to routine GC/MS. The principle of the operation has been illustrated in Figure 3. In essence, effluent from the first column is injected at a fixed frequency into a single secondary column. The frequency of transfer is analogous to the scan rate in GC/MS. Dispersion in 2-D GC occurs according to stationary phase interaction as opposed to “mass dispersion” in GC/MS. Both processes are quite similar in principle. The implementation of comprehensive 2-D GC however is quite difficult. The major challenge comes from the need to inject the effluent into the second column as a series of narrow pulses, followed by rapid elution. Narrow pulses can be generated by several methods. The most straightforward approach is to use a valve, fluidic switch or similar device. Diaphragm-type valves can produce precisely defined pulses at a high rate and are quite suitable for this purpose. Unfortunately, most of the sample is lost. A more promising approach is the use of a modulator which is capable of both focusing and reinjection of the analyte. Figure 10 shows the basic arrangement of a comprehensive two-dimensional gas chromatograph based on this principle. The modulator accessory is commercially available. Components eluting from the first column are focused on a short section of a fused silica column which is coated with a thick layer of stationary phase. This device, called a modulator tube, is inserted between the columns. The components are released from the modulator tube and injected into the secondary column by application of heat transferred from a mechanical sweeper. The rate of movement of the sweeper is limited by the heater temperature and the heating time constant of the column. The primary column is usually a conventional capillary column which is programmed slowly. The secondary column typically is a narrow-bore, high-speed column capable of elution within a few seconds or tens of seconds. High speed is necessary because elution from the secondary column must be complete or nearly complete before the next injection can be made. Figure 11 presents some details on the formation of these pulses. The process can be divided into four segments.

1. Accumulation. The analyte moving into the modulator tube forms a sharp leading edge due to stationary phase focusing.
2. Cut. The slotted heater moves over the modulator tube holding the adsorbed sample and brings the substances dissolved in the stationary phase back into the gas phase.

3. Focus. The front of the “plug” moves slightly ahead of the steep temperature gradient formed by the slotted heater. It is self “sharpening”.

4. Launch. The “plug” eventually reaches a section of uncoated tubing or the secondary column. The phase ratio and carrier gas velocity in this section are high. The substances start to move at high speed.

All of these processes overlap and are coordinated. Several critical steps must be harmonized to make this complicated procedure a success. The components in the modulator tube must be heated rapidly, i.e. the thermal response of the system must be fast. This requires that heat transfer is rapid. In essence, it is necessary to heat and cool the modulator tube in a fraction of a second. Fortunately, fused silica has low thermal mass. Time constants of the order of 100 ms can be achieved, depending on factors such as column dimension and the temperature of the slotted heater. Effective heat transfer requires that the distance between the surfaces of the slotted heater and the modulator tube is minimized. Factors such as the dimension of the connectors between the columns and the modulator tube become critical.

Prior to the invention of the rotating heater, a metal coated electrically heated column was used for GC × GC modulation. Electrical heating of metal coated modulator tubes seems to be an attractive alternative to mechanical devices. Thermal modulation was the first approach that was used to produce narrow pulses. Electrical heating is attractive because the amount of transmitted energy can easily be controlled. It is, however, difficult to match the thermal requirements of the fused silica with the thermal mass of the surrounding film of metal. Relatively high temperatures are required for the formation of narrow pulses. This places considerable stress on the fragile components and causes frequent burnout. Metal lined tubing and miniature wire coil heaters are more stable but heat transfer characteristics become unsatisfactory because of high thermal mass.

Another approach for the formation of pulses by mechanical means has also been offered. It is based on cryogenic focusing and uses a movable trap. The accumulation and focusing phases are combined.

**Figure 11** Detailed view of chemical pulse formation: (a) accumulation; (b) cut; (c) focus; and (d) launch. PT, phase termination. (Reproduced by permission from Phillips et al.)

**Figure 12** Effect of thermal modulation or peak widths and peak intensities. The low and broad peak is not modulated. The high and sharp peaks are the result of modulation of the same compound. (Reproduced by permission from Beens et al.)
The substances are moving toward a gradient of low temperature and are retained until the cryotrap is displaced by mechanical movement. The substances are then launched by being exposed to the temperature of the environment in the GC oven. An external source of heat is not required. This system is referred to as a longitudinally modulating cryogenic system (LMCS). It seems to be versatile and effective.\(^{(128–130)}\) A number of advantages are claimed for this approach.\(^{(131)}\) The method seems to be particularly suitable for highly volatile compounds which may not experience the necessary degree of stationary phase focusing on a thick film modulator tube at ambient temperature. Data available at this time are insufficient to predict which of the two types of mechanical modulators will eventually become more successful.

Modulation provides some unexpected benefits. It is possible to reverse the effects of peak dispersion caused by

---

**Figure 14** (a) Total ion GC × GC/MS of a marine diesel fuel sample. The x-axis (min) reflects volatility based retention on the apolar primary column (13 m × 0.10 mm × 1.3 µm, dimethylpolysiloxane); the y-axis (min) reflects polarity based retention on a polar secondary column (2 m × 0.10 mm × 0.10 µm, cyanopropylmethylpolysiloxane). Both columns programmed 30–250 °C at 0.5 °C min\(^{-1}\). Run time 440 min. Thermal modulator programmed at \(\Delta T = 100^\circ\)C above oven temperature, velocity 0.2 rev s\(^{-1}\), period 14.4 s. MS conditions: scan 45–350 amu, 2.43 scans s\(^{-1}\). (b) Enlargement of box 1. (c) Enlargement of box 2. (d) Enlargement of box 3. The peaks in the chromatogram are represented in the bottom window by shapes corresponding to the molecular ion of each peak. (Reproduced by permission from Frysinger et al.\(^{(140)}\))
migration in the primary column. In essence, a wide peak can be sharpened into a series of narrow peaks. Figure 12 shows an overlay of peaks from two experiments. A wide peak with a peak width of approximately 30 s is focused and periodically reinjected into a secondary column in the form of narrow pulses. Because of the law of mass conservation, peak areas must be the same. The slices from the individual focus/reinjection cycles must be integrated and summed for quantitation. The benefit of the process is a better signal-to-noise ratio and thus lower detection limit.

At the present time, data acquisition and presentation of signals of the type shown in Figure 12 still present problems. One must keep in mind that an enormous volume of data is generated at a very rapid rate. The situation may be comparable to the early days of GC/MS. Most electrometers on currently available gas chromatographs do not allow proper filtering and noise rejection. In conventional GC instrumentation, the analog signal from the detector is translated into digital pulses which are subjected to a low frequency pass filter below being reconverted into the final output signal. This process produces large time constants and conventional equipment may not be capable of following rapidly changing signals. To overcome the problem, the signal has to be extracted from the electrometer board before the band pass filter. This results in increased noise. Detection limits are improved but the gain is not as significant as one may expect by looking at Figure 12. Nevertheless, this problem can be solved, in principle, by the introduction of fast amplifiers. A new generation of fast electronics is currently being introduced to the market.
Quantitation and data treatment in comprehensive 2-D GC require a different approach. Figure 13 shows an excerpt from a hypothetical chromatogram. Each peak is cut into slices which are then subjected to individual analysis in the second dimension. Signal A consists of a single component whereas signal B contains two individual substances. The data can be displayed as three-dimensional plots or as contour plots. Integration requires summation of individual slices.

Groups of components with similar properties tend to fall into well defined planes within the chromatogram. This is a consequence of intrinsic sample dimensionally, a property predicted by Giddings. Groups of components with similar structural features can thus be integrated by delineation of boundary conditions. The chromatograms produce order. Figure 14(a) shows an excerpt of a comprehensive 2-D GC chromatogram reflecting the C\textsubscript{10} to C\textsubscript{20} range of a petroleum distillate. This chromatogram is particularly interesting because it represents the first application of a mass spectrometer as a detector in comprehensive 2-D GC. The x-axis and y-axis represent retention in the primary and in the secondary dimension, respectively. Components at the bottom of the chromatogram experience the lowest retention on the polar secondary column and are thus the least polar substances in the mixture. They represent alkanes. Figure 14(b) shows an enlargement from the chromatogram section delineated by box 2. Peaks A, B, and C are situated slightly above the group of substances at the bottom. They represent a homolog series of alkylcyclohexanes which are slightly more polar than n-alkanes and most of the branched alkanes. Figure 14(c) shows a vertical slice (box 1). Peaks E and F have the lowest and peak A has the highest retention on the polar stationary phase. These compounds, representing different structures, have been separated according to polarity. They have similar boiling points and are thus unresolved on the apolar stationary phase. Figure 14(d) corresponds to box 3 which is displaced in the y-direction. These substances are obviously quite polar. The schematic presentation at the bottom of the figure shows that compounds sharing similar features fall into well defined spaces. Mass spectra confirm the assignments. The order produced in the process can be a valuable aid in
identification. Software for display and integration of flame ionization detection based data has now been developed. It includes options such as interactive zoom in/zoom out features, visual clues for peak start/peak stop, peak area integration routines, etc. The distribution of components in two-dimensional space can be predicted.

4.1 Operational Aspects and Future Developments

At the present time, comprehensive 2-D GC is still in its early stages of development. The practicality of MS detection has been demonstrated but the scan rates of conventional mass spectrometers are too slow to deal with the high rate at which the data are being generated. A new generation of rapid scan time-of-flight (TOF) type mass spectrometers can solve this problem. These instruments are capable of generating up to 100 scans per second. Flame ionization detection is the most practical approach at this time. It is necessary to adapt and miniaturize other detectors, in particular the electron capture detector, to the environment of comprehensive 2-D GC. Comprehensive two-dimensional gas chromatograms of complex mixtures such as PCBs are ordered. Components are thus more easily identified than in chromatograms where the order of elution is not structured. Chemometric methods of data treatment such as the Generalized Rank Annihilation Method (GRAM) can be used to deconvolute reduced resolution chromatograms. The required run-to-run retention time precision, signal intensity and similar factors can be met by comprehensive 2-D GC. Independent temperature programming of the individual columns can provide optimal use of space and provide truly orthogonal information.

Many chromatographers are not familiar with comprehensive 2-D GC. Applications have been limited to demonstrations in the fields of petroleum analysis. Two short reviews have been published in the mid-1990s.
20
GAS CHROMATOGRAPHY

on the subject matter. (28,144) A thorough up-to-date review emphasizing fundamental aspects of 2-D GC has appeared after original submission of this article. (145) It was initiated by J.B. Phillips who has since passed away. J. Beens consequently finished the review. The future development of comprehensive 2-D GC looks very promising.

ACKNOWLEDGMENTS

I would like to thank E.B. Ledford and G.S. Frysinger for valuable input and help with some of the figures and references. The late J.B. Phillips freely shared his experiences and provided unpublished data. J.H. Sandy provided the data for Table 2.

The success of a gas chromatographic analysis mostly depends on the sample preparation procedure. Biological and environmental samples are not suitable for direct analysis. Organic analytes can be separated from matrices by extraction methods such as gas–solid, liquid–liquid, solid–liquid, purge-and-trap, headspace, solid-phase (SPE), solid-phase microextraction (SPME), supercritical fluid (SFE) and Soxhlet extractions. These extraction methods are called phase separation methods. Matrix solid-phase dispersion (MSPD) is a special highly efficient phase separation procedure for biological matrices such as meat, liver, muscle, vegetables, etc. The aim of the extraction procedure is not only separation of organic analytes from matrices but also concentration in another phase.

If the organic analytes contain protic (active) hydrogen (alcohols, carboxylic acids, amines, oxo compounds, etc.) some derivatization reactions, such as acylation, alkylation and silylation, need to be carried out first. The aim of the derivatization methods is to increase the sensitivity of detection and thermal stability of the organic analytes. The other aspect of derivatization is to reduce the polarity of the compounds.

1 INTRODUCTION

The most important part of gas chromatographic analysis is the preliminary sample preparation process. The sample preparation procedures for gas chromatography (GC) are divided into two main types:

- extraction methods
- derivatization methods.

The original samples are often too diluted, contaminated, complex, etc. and are thus not suitable for injection into the gas chromatograph.

In addition to the chemical properties of the samples, their physical characteristics also influence the preparation procedures. To analyze water or soil samples, some kind of extraction method is needed. Often, in order to increase the sensitivity of the analytical method, a derivatization step is included, particularly after extraction. The aim of the extraction is the separation of organic analytes from matrices and their concentration in another phase. Derivatization methods need to be carried out first if the compounds contain protic (active) hydrogens (alcohols, oxo compounds, carboxylic acids, phenols, amines, etc.) as these compounds are not suitable for direct gas chromatographic analysis.

The most relevant extraction and derivatization methods are summarized in this article.

2 GAS SAMPLE PREPARATION

2.1 Monitoring Airborne Contaminants in the Atmosphere

Airborne organic contaminants can be collected on the surface of different types of adsorbent materials, such as activated charcoals, polymer adsorbents, molecular sieves, etc. or absorbed in suitable solvents. The adsorption of organic vapours on solids is used as a preconcentration method. The recommended collecting devices are adsorbent tubes, filter cassettes, and impingers. The sampling process is carried out with an oil-free sampling pump. The pumping time of the air sample
depends on the characteristics of the trapped compounds. The trapped compounds can be desorbed from the adsorbents with a solvent or by thermal desorption methods before analysis. These methods of monitoring organic vapours are used for occupational hygiene control.\(^1\)

### 3 LIQUID SAMPLE PREPARATION

#### 3.1 Liquid–Liquid Extraction

This method is used to analyze water samples. Although the instrument (a separation funnel) is simple, the method can be expensive due to the high cost of ultrapure solvents. A given volume of the water sample is shaken with a given volume of a suitable organic solvent so that organic micropollutants are transferred mainly into the organic phase (Figure 1). To increase the efficiency of the extraction and to avoid foam developing, sodium chloride is added to the sample before extraction. After separating the phases, most of the organic solvent is distilled off. This concentrating process is carried out in a Kuderna–Danish apparatus (Figure 2). The degree of concentration is calculated from the ratio of the initial volume of the sample to the volume of the concentrated sample. For example, for a 1 L water sample which is finally concentrated to 1 mL, the degree of concentration is 1000 for both micropollutants and impurities of the solvent. After a large number of extractions, storage and handling of solvent wastes can be environmentally hazardous. The Kuderna–Danish apparatus is used for the extraction of nonvolatile or less volatile components, because its operating temperature is higher than the boiling point of the solvent. Liquid–liquid extraction is losing its importance as nonsolvent extraction methods become more and more popular.\(^2\)

![Figure 1 Separation funnel.](image1)

![Figure 2 Kuderna–Danish apparatus.](image2)

#### 3.2 Purge-and-trap Technique

This method is excellent for extracting volatile organic components from water. Ultrapure gas is bubbled through a 5–20 mL water sample. Volatile organic compounds (VOCs) move with the gas bubbles and the flow is driven into a heatable adsorber column, where components adsorb at room temperature. Then, by heating the adsorber column, these components are forced into a cooled capillary column, where they condense. This process is called cryofocusing. Finally, by heating the capillary column to 200–300 °C, the components pass into the gas chromatograph. Benzene homologs benzene, toluene, ethylbenzene, and xylenes (BTEX) and volatile halogenides are analyzed with this method according
to the United States Environmental Protection Agency (USEPA) (Figure 3).

Since the whole sample can be analyzed, this extraction method is highly sensitive, plus it has the advantage of being a nonsolvent technique. The detection limit is nanograms per liter in the case of a few milliliter water sample. Commercial instruments are automatic.

3.3 Headspace Extraction

This method is used for extracting volatile compounds. The water sample is placed into a vial, which is put into a thermostat. A sample is then extracted from the headspace at a given temperature, between 40 and 60 °C. Two techniques exist, known as static and dynamic (Figure 4). Headspace extraction is a nonsolvent and automatic method. In certain cases the purge-and-trap technique can be replaced by this method, because of its high sensitivity.

3.4 Solid-phase Extraction

With the exception of volatile compounds, the SPE method is widely used. The sample is passed through a short, packed column, where organic components adsorb or absorb (Figure 5). Then they are eluted with a small amount (2–10 mL) of solvent. Three types of packing material exist:

1. normal phase (mainly SiO₂, Al₂O₃, silicates and other inorganic adsorbents)
2. reverse phase, which contain chemically bonded liquid film on an inorganic, solid support
3. ion-exchange packing.

Depending on the chemical properties of the film, a preseparation (clean-up) phase may be possible.

3.5 Solid-phase Microextraction

Solid-phase microextraction (SPME) is the most rapidly developing field of environmental analysis. SPME techniques were originally used for extracting water samples, but the method is also suitable for examining the headspace of solid samples. This method is simple, fast and quite efficient. Only 5–20 mL of sample is necessary, while no solvent is needed. The degree of concentration is 10²–10⁵, depending on the circumstances. The essential part of the instrument is a thin, fused silica fiber with chemically bonded organic film on its surface (Figure 6). When the fiber is immersed into the water sample or kept...
in the sample headspace for a given time (2–30 min) with vigorous stirring, organic micropollutants absorb in the film, depending on their distribution coefficients. Finally, using the holder, the fiber is placed into the injector of a GC instrument, where components desorb at high temperature (200–300 °C).\textsuperscript{15}

\section*{4 SOLID SAMPLE PREPARATION}

\subsection*{4.1 Soxhlet Extraction}
This is a classical extraction method used for solid samples. Vapor from the solvent moves up from a flask, which is heated. The vapor condenses on a condenser, and drops of the solvent fall back onto solid sample particles. Once the side-vessel is full, the solvent runs back to the bottom flask (Figure 7). This method is a so-called exhaustive extraction, but is very time-consuming (8–48 h). The method can be automated, and in commercial instruments it is possible to extract more than one sample at the same time.

\subsection*{4.2 Supercritical Fluid Extraction}
In a phase diagram of a one-component system we can see the temperature and pressure intervals, where different phases are thermodynamically stable (Figure 8). The values at which two certain phases can be in equilibrium are given by the barrier lines. Above a given temperature ($T_c$, critical temperature) the two phases become one. Under special circumstances, when both temperature and pressure are higher than the critical values, materials are said to be in a supercritical state. Supercritical fluids have properties of both liquids and gases. Their diffusion and viscosity constants are similar to those of gases, while their densities are closer to those of liquids (see Table 1). Supercritical fluids are excellent solvents, because it is easy to manipulate their solvation properties by changing the temperature and pressure. A scheme of the supercritical fluid extraction (SFE) process can be seen in Figure 9.

In the field of solid sample analysis, SFE is becoming more and more popular. Its efficiency is similar to that of Soxhlet extraction, while the process lasts only 20–30 min.
Supercritical CO₂ is the most common solvent. The method can be automated\(^6,7\).

### 4.3 Ultrasonic-assisted Solid–Liquid Extraction

This sample preparation method is used for extracting compounds from contaminated soil samples. The process is based on cavitation in liquid media. The bubble generation caused by cavitation is similar to boiling and it contributes to the dispersion of the solid sample. Usually the ultrasonic source is immersed into the mixture. Since the moisture content of the solid sample is rarely high, it is recommended that the ultrasonic-assisted extraction is begun with a polar organic solvent (such as acetone) and continued with a nonpolar one (such as n-pentane).

Fields of application are with total petroleum hydrocarbons (TPH), GC, BTEX, chlorinated VOCs, polycyclic aromatic hydrocarbons (PAH) and polychlorinated biphenyls (PCB).

### 4.4 Matrix Solid-phase Dispersion

Matrix solid-phase dispersion (MSPD) is a highly efficient sample preparation process for use with solid matrices. It is a microscale extraction technique, which usually needs 0.5–1 g of sample. This method was developed to extract
GAS CHROMATOGRAPHY

Homogenize blend to prefitted reservoir Tap to settle bed Gently insert top frit with frit inserter Elute interferences

Figure 10 MSPD procedure.

additive residues from biological matrixes such as meat, liver, muscle, vegetable, etc.

Homogenization of the sample is carried out with a bulk-bonded silica-based sorbent in a mortar, and mechanical shearing is used to disrupt the structure of the tissue (Figure 10). The homogenization step is followed by tedious liquid–liquid extraction procedures. Using a suitable solvent this method is highly selective.\(^{(8)}\)

5 DERIVATIZATION METHODS FOR GAS CHROMATOGRAPHY

The aim of derivatization methods for GC is the substitution of active functional groups to increase or decrease volatility, to improve detectability and thermal stability, and to reduce the polarity of molecules.\(^{(9,10)}\) There are three main methods in this field:

- acylation
- alkylation
- silylation.

5.1 Acylation

The acylation method is used for compounds that contain OH, SH and NH groups, and reduces the polarity of these molecules. General acylation reagents are perfluoro acid anhydrides, such as trifluoroacetic anhydride and pentfluoropropionic anhydride, and fluoroacetamides, such as \(N\)-methylbis (trifluoroacetamide). The detectability is increased by electron capture detection (ECD).

5.2 Alkylation

The alkylation procedure is used to modify acidic hydrogens, such as phenols and carboxylic acids. Perfluoroalkyl reagents improve the detectability while other alkylation reagents, such as dimethylformamide, reduce the polarity of compounds.

5.3 Silylation

Silylation is substitution of an active hydrogen for a trimethylsilyl group. The silylated derivatives are more volatile and more stable. This method reduces the polarity of the compound and reduces the possibility of hydrogen bonding. Many hydroxy, carboxy and amino compounds have been successfully measured after silylation. General silylation reagents include dimethylchlorosilane, trimethylsilyl-N,N-dimethylcarbamate, trimethylchlorosilane, trimethylsilylimidazole, etc.

Infrared Spectroscopy: Introduction

Marianne L. McKelvy
The Dow Chemical Company, Midland, USA

Infrared (IR) spectroscopy provides one of the most versatile and useful techniques for the qualitative and quantitative characterization of most types of materials found in the solid, liquid or gaseous state. The general utility of this technique is reflected in the fact that many sections of the Encyclopedia contain articles dealing with the application of IR spectroscopy to that particular area, for example, the characterization of polymeric materials. This section, then, focuses on basic theory of IR spectroscopy and spectral techniques that may be applied to a broad range of chemical systems.

The origins of IR spectroscopy lie in the vibrational motions of atoms within a molecule. The sharply defined frequencies of these vibrations fall within the IR region of the electromagnetic spectrum, from 14,000 to 20 cm\(^{-1}\). The most useful range for general problem solving lies between 4000 and 400 cm\(^{-1}\), the mid-IR range. Specific applications in the near-IR, the region above 4000 cm\(^{-1}\), are discussed in other sections of this Encyclopedia, most notably in articles titled Near-infrared Spectroscopy, In Vivo Tissue Analysis by; Near-infrared Spectroscopy in Food Analysis; Near-infrared Spectroscopy in Analysis of Crudes and Transportation Fuels; Near-infrared Spectroscopy of Polymers and Rubbers and Infrared Spectroscopy in Process Analysis.

When a sample is irradiated with IR energy, that energy will coincide with vibrational frequencies of functional groups within the molecule. These vibrational motions include a change in the dipole moment of the molecule, IR absorptions occur. The pattern of these absorptions for a molecule, the IR spectrum, is generally unique for a particular compound. Comparison of the IR spectrum of an unknown material with that of known standards is a powerful identification tool. In the absence of standard spectra, the fact that many functional groups (C=O, C≡N, –OH, C=C, etc.) possess absorption bands that are characteristic of that moiety can be used to identify the material. The article Interpretation of Infrared Spectra, A Practical Approach discusses these concepts in detail.

Since the intensity of spectral absorbance is directly proportional to the amount of sample present (Beer’s Law), IR spectra can also be used to make quantitative determinations of the amount of individual components in a sample mixture. These procedures can be as simple as a calibration curve that measures the intensity of a band in a sample with known path length to complex determinations of multiple components in a matrix. However involved the analysis, the existence of well-defined standards of the materials to be characterized is critical for good quantitative determination. The Encyclopedia’s section on Chemometrics discusses these quantitative approaches in detail.

Modern instrumentation for acquisition of spectral data in the mid-IR largely consists of Fourier transform infrared (FTIR) instruments. The improved signal-to-noise and enhanced data acquisition speed of these devices has resulted in the replacement of wavelength-dispersive instruments with FTIR instruments. Additional technological improvements over the last decade have significantly lowered the cost of these instruments, making them highly affordable.

This improvement in signal-to-noise has allowed for the introduction of sampling accessories and coupled devices that further expand the analytical capability of the IR technique. Reflectance accessories have improved the ability to analyze surfaces at various depths of penetration. The IR microscope allows the routine collection of IR spectra of samples as small as ten micrometers. Reflectance accessories for the microscope extend this capability to surface analysis as well. Coupling of gas and liquid chromatographic systems to IR spectrophotometers has extended the range of sample types available for analysis. In addition to the articles in this section, applications of gas chromatography/infrared (GC/IR) and liquid chromatography/infrared (LC/IR) to the polymer and food industries are discussed elsewhere in the Encyclopedia (Liquid Chromatography in Food Analysis; Gas Chromatography in Analysis of Polymers and Rubbers; Inverse Gas Chromatography in Analysis of Polymers; Coupled Liquid Chromatographic Techniques in Molecular Characterization).

Spectral Data, Modern Classification Methods for discusses the difficulty of classifying spectral data, where there are a large number of variables (i.e. wavelengths) represented in each spectral case. Two strategies for dealing with this problem are presented: the use of high dimensional classifiers and reduction of the number of variables using feature extraction methods.

The article Cavity Ringdown Laser Absorption Spectroscopy, although not a traditional IR technique, is an introduction to this developing variant on absorption spectroscopy. This new technique promises to bring improved sensitivity to the measurement of chemical species in a broad range of environments, from molecular beams to plasmas.

Much of this section deals with the application of particular instrumental techniques to broad systems of chemical materials. In Emission Spectroscopy, Infrared, the theory of IR emission spectroscopy, spectrometer design and
experimental considerations for measurements of solids, liquids and gases are discussed.

Gas Chromatography/Infrared Spectroscopy presents light pipe, matrix isolation and direct deposition interfaces for GC/IR. Applications to several industrial problems are discussed. The importance of spectral searching and databases is considered. Finally, the future of GC/IR and double-hyphenated techniques is presented.

Infrared Reflection–Absorption Spectroscopy provides an overview of this technique and the analysis of material surfaces. Theory, experimental and instrumental considerations are discussed. Finally, this technique is compared to other surface techniques that provide vibrational spectroscopic information.

Interpretation of Infrared Spectra, A Practical Approach begins with detailed discussion of the origins of IR spectra and then examines the various functional group frequencies in detail. The third portion of the article is devoted to a discussion of the importance of sample context – history and chemistry – in the analysis. The paper concludes with some simple guidelines and thought processes to assist with spectral interpretation.

Theory of Infrared Spectroscopy presents a discussion of the theoretical basis of IR spectroscopy, group theory, and discussion of solvent effects and the impact of hydrogen bonding, crystallinity and chain length of polymers on IR spectra.

Liquid Chromatography/Infrared Spectroscopy discusses techniques for both flow cell and solvent elimination approaches to LC/IR. Applications of both types of systems, including gel permeation chromatography, on-line measurements and flow injection analysis, are reviewed. Discussion of future directions for this technique is included.

The theory and design of the IR microscope are presented in Microspectroscopy. A discussion of sampling techniques useful in the preparation of specimens for the microscope is included. Reflection measurements are discussed in great detail. IR imaging, including a discussion of current array detector technology as well as the outlook for future development, is included.

The article Vibrational Spectroscopy for the Analysis of Geological and Inorganic Materials pays particular attention to sampling techniques for these materials. Spectral assignments for metal oxides and salts, hydroxides and silicates are discussed in detail. Numerous references to historic/archaeological and planetary applications of IR spectroscopy are also cited in this paper.

Spectral Databases, Infrared presents the history and application of spectral databases to the interpretation of IR spectra. Many references to published spectral collections and digitized spectral libraries are included. Various algorithms for spectral identification are discussed in detail.

Cavity ringdown spectroscopy (CRDS) has developed rapidly during the last two decades and has been implemented for a variety of applications ranging from fundamental spectroscopic studies, trace chemical detection for environmental monitoring, combustion flame chemistry and plasma diagnostics, elemental and isotopic measurements, breath gas analysis, and fiber ringdown chemical and physical sensor development. A host of chemical species, including atoms, ions, molecules, clusters, and free radicals, have been studied by CRDS. The experimental ringdown scheme has also evolved from an original mirror-based format to various new forms for detection and analysis of analytes in either gas phase or liquid solutions. Recent research effort has also extended the CRDS approach for fiber optical sensor development. CRDS has become a mature spectrometric technique for a range of prototype and commercial instrumentation. This article provides a review of the latest developments in CRDS applications, specifically emphasizing new trends in elemental and isotopic analysis, plasma diagnostics, breath gas analysis, and new fiber ringdown techniques for sensor development. The introduction of cutting-edge laser sources into CRDS methods, the combination of CRDS with conventional analytical tools, and current CRDS instrumentation are also briefly discussed.

1 INTRODUCTION

In the original implementation of CRDS, a laser pulse was trapped in a high-finesse optical cavity formed by two high-reflectivity mirrors. The many round trips of the pulse within the cavity enhanced the absorption path length for a sample gas in the cavity by several orders of magnitude. The decay time for light in the cavity was used to determine optical absorption rather than the change in intensity of the light. Following its introduction by O’Keefe and Deacon in 1988, CRDS has been implemented for the spectroscopic study of numerous species, including molecules, free radicals, clusters, atoms, and ions in a variety of...
environments, such as chemical reaction cells, supersonic beams, high-temperature plasmas/flames, and material processing chambers. Research and applications relevant to CRDS have expanded the original experimental scheme to the use of novel optical cavities, light sources, methods of cavity excitation and shutoff, and combinations with other traditional instruments. Although ringdown-based commercial instrumentation has been realized, thus far, only in semiconductor manufacturing, this technology has already shown much promise in a wide variety of application areas, such as detection of trace species in environmental monitoring, plasma and flame chemistry diagnostics, high-sensitivity elemental and isotopic measurements, breath gas analysis for medical diagnostics, and fiber ringdown techniques for sensor development. CRDS has been applied in spectral regions ranging from the ultraviolet to the infrared by using different laser sources. CRDS coupled with a frequency comb technique demonstrated the capability of measuring numerous chemical species simultaneously.

More than 10 review papers on CRDS have been published to date. The first historical overview of CRDS was published in a book edited by Busch and Busch. This book contains many of the early publications on various aspects of CRDS. Berden et al. have given a comprehensive review on experimental schemes and applications of CRDS. Scherer et al. reviewed early publications in fundamental spectroscopic studies using CRDS. Miller and Winstead have reviewed atomic and analytical applications of CRDS. Wagner et al. have reviewed early CRDS studies in the infrared spectral region. The application of CRDS for kinetics studies has been reviewed by Atkinson. The technological innovations of cavity ringdown have been discussed in Vallance’s review. Paldus et al. have given a historical review of CRDS development. Recently, Mazurenka et al. have reviewed the powerful application of diode lasers in CRDS and its variant, cavity enhanced absorption spectroscopy (CEAS), also widely known as an integrated cavity output spectroscopy (ICOS). Very recently, Wang has reviewed plasma cavity ringdown spectroscopy (P-CRDS) for elemental and isotopic measurements (Figure 1).

The purpose of this article is to provide an update of the previous review on the application of CRDS in analytical and atomic spectroscopy by Miller and Winstead in 2000. The discussion attempts to cover a wide range of applications of CRDS with a new emphasis in this article on environmental monitoring, the latest developments in P-CRDS for elemental and isotopic measurement, and combustion flame chemistry and plasma diagnostics. Emerging medical applications of CRDS and new fiber ringdown techniques for optical sensor development are new additions to the article. Finally, a brief update of the current status of ringdown commercialization/instrumentation is also presented.

2 THEORY AND OPERATING PRINCIPLES

2.1 Cavity Ringdown Spectroscopy

The number of experimental methods that are essentially based on the CRDS principle continues to grow. However, in its original form, CRDS is implemented by injecting and trapping a laser pulse in a stable optical cavity, which is formed by two highly reflective mirrors. The intensity of the light in the cavity decays exponentially with time at a rate determined by the round-trip losses experienced by the laser pulse. This intensity decay is monitored using a photomultiplier tube or a photodiode placed behind the second mirror, and the ringdown time is usually determined by fitting the observed waveform to a single exponential function. A schematic diagram of a typical experimental system is given in Figure 2. For the simplest case, when the dominant losses are the mirror reflectivity and absorption from a sample gas in the cavity, the time constant for the exponential decay is given approximately by

\[
\tau = \frac{d}{c(1 - R) + \alpha l_s}
\]

where \(d\) is the cavity length, \(R\) is the reflectivity of the cavity mirrors, \(\alpha\) is the familiar Beer’s law absorption coefficient of a sample in the cavity, \(l_s\) is the length of the optical path through the sample, and \(c\) is the speed of light. For a gas filling the entire cavity, \(d = l_s\). As the laser wavelength is varied, the ringdown time will decrease upon tuning to an absorption wavelength of the sample (e.g. when \(\alpha\) increases). Alternatively, when the laser wavelength is fixed on resonance with an absorption wavelength of the sample, variations in \(\alpha\) caused by changes in the analyte concentration are reflected in the ringdown time.
A “back-of-the-envelope” understanding of the time behavior from Equation (1) can be gained from an examination of Figure 2, where the first few passes of a laser pulse through the cavity are depicted. When a laser pulse is incident on the first cavity mirror, most of the energy is reflected away from the cavity. Assuming that the fraction of the original pulse that enters the cavity has intensity $I_0$, after one pass through the sample gas, the intensity will be reduced according to Beer’s law to $I = I_0 e^{-\alpha l}$. Following reflection from the second cavity mirror, the intensity will be reduced by the finite mirror reflectivity to $I = I_0 R e^{-\alpha l}$. After $n$ round trips through the cavity and substituting $R^{2n} = e^{2\ln R}$, the intensity will be

$$I = I_0 R^{2n} e^{-2n\alpha l} = I_0 e^{-2n(\ln R + \alpha l)}$$

(2)

If the cavity is long enough that the pulse never overlaps itself (e.g. longer than one-half of the physical length of the laser pulse), a series of separated pulses decaying in time will be detected according to Equation (2). In many cases, due to electronic response time or the use of shorter cavities, separated pulses are not detected, but rather a continuous exponential decay. The peak envelope of the separated pulses or the time constant for a continuous exponential decay can be found by converting from the discrete variable $n$ to a continuous variable $t$ such that $n = t/T$, where $T = 2d/c$ is the pulse round-trip time in the cavity. In this case, we have

$$I = I_0 e^{-\alpha t(-\ln R + \alpha l_s)/d}$$

(3)

Of course, the absolute intensities detected by the Photomultiplier tube (PMT) are reduced by an additional factor of the mirror transmission, but this does not affect the time behavior of the exponential decay. From Equation (3), we see that the characteristic time for the laser pulse decay is given by Equation (4):

$$\tau = \frac{d}{c(-\ln R + \alpha l_s)} \approx \frac{d}{c[(1 - R) + \alpha l_s]}$$

(4)

as given in Equation (1). While this analysis does not provide a complete development of the technique, it captures the essential elements that yield the excellent sensitivity offered by CRDS. The performance and some limitations of CRDS and this simple model are discussed. Note that if the ringdown time is measured in the absence of a sample gas in the cavity (e.g. $\alpha = 0$), the reflectivity of the mirrors can be determined. Once the mirror reflectivity has been measured and a sample introduced, CRDS provides an absolute measure of the absorbance $\alpha l_s$, from which the absolute density $n$ of the absorber is determined by

$$\alpha l_s = \sigma n l_s$$

(5)

where $\sigma$ is the absorption cross section of the absorber in the laser wavelength. This self-calibrating feature can serve as a great benefit in comparison to other high-sensitivity techniques, such as laser-induced fluorescence (LIF) or resonantly enhanced multiphoton ionization (REMPI).

2.2 Sensitivity

The high sensitivity of the CRDS technique stems significantly from the large number of passes the light pulse makes through the sample in the cavity. For mirrors of 99.99% reflectivity in a 1-m-long cavity, the ringdown time is approximately 33.4 $\mu$s for an empty cavity. This is equivalent to a 10-km path length traveled during the first time constant. For analytical applications, the detection sensitivity of CRDS is normally characterized by the detection limit, which is determined by a minimum detectable absorbance, $\sigma n l_s$:

$$\text{Absorbance} = \sigma n l_s = (1 - R) \frac{\Delta \tau}{\tau}$$

(6)

where $\Delta \tau$ is the difference between $\tau_0$ (the decay time with no analyte) and $\tau$ (the decay time with analyte present). Equation (6) indicates that for a given mirror
reflectivity, the measured absorbance depends upon the quantity, $\frac{\Delta \tau}{\tau}$. When $\tau$ is replaced by $\tau_0$ and $\Delta \tau$ replaced by $\sigma_\tau$ (one standard deviation of the measured ringdown time), then the absorbance in Equation (6) represents the minimum detectable absorbance based on a $1\sigma_\tau$ criterion. Note that in most cases the detection limit is derived on the basis of the standard $3\sigma_\tau$ criteria, namely,

$$A_{\text{min}} = (1 - R) \frac{3\sigma_\tau}{\tau_0}$$  \hfill (7)

Clearly, Equation (7) demonstrates that increased mirror reflectivity will improve $A_{\text{min}}$. Here, $\sigma_\tau$ and $\tau_0$ may be the values determined after averaging a number of individual ringdown measurements, further improving $A_{\text{min}}$. Alternatively, sensitivity can be also characterized by a detection limit that explicitly includes the assumption that the single decay measurement uncertainty is improved by averaging over $N$ ringdown events,$^{79}$ as given in Equation (8):

$$A_{\text{min}} = (1 - R) \frac{\Delta \tau}{\tau \sqrt{N}}$$  \hfill (8)

If the measuring time is restricted to 1 s, then $N$ is replaced by data collection frequency, $f$. Thus, the unit of $A_{\text{min}}$ is Hz$^{-1/2}$. This is also called noise-equivalent minimum detectable absorbance.

Examining Equations (1) and (5), one can see that the detection sensitivity is determined by a ringdown system’s physical parameters, such as cavity length, sample path length, mirror reflectivity, and by the system electronic noise. Higher mirror reflectivity, longer sample path length, and lower electronic noise will improve detection sensitivity. The combined effect of the electronic noise with the optical alignment of the ringdown system is often experimentally characterized by $\sigma_\tau/f$, which is typically referred to as the ringdown baseline noise. For a pulsed-CRDS system, the baseline noise is typically larger than 0.3%. However, for a continuous wave cavity ringdown spectroscopy (CW-CRDS) system, the baseline noise can be much lower. The lowest baseline noise reported thus far is $2.7 \times 10^{-4}$ obtained in a near infrared (NIR) CW-CRDS system with an average over 300 ringdown events.$^{54}$ Detection sensitivity on the order of $1 \times 10^{-8}$ (absorbance) demonstrated in the early studies$^{80,81}$ can now be readily achieved with the availability of ultrahigh reflectivity mirrors.

### 2.3 Cavity Design and Cavity Ringdown Spectroscopy Implementation

The simple model outlined in Section 2.1 neglects a number of other potentially important considerations. First, to achieve true single exponential behavior, the conditions for Beer’s law behavior must be fulfilled.$^{78}$ These conditions include requiring that the frequency linewidth of the laser source be narrower than the absorption linewidth. If the laser source linewidth is broader than the absorption, then only that part of the laser frequency resonant with the absorption will be attenuated. The nonresonant frequencies of the laser pulse will continue to propagate in the cavity without being absorbed, leading to distinctly nonsingle exponential behavior. In the case where the absorption and laser linewidths are nearly the same, CRDS can still be used to extract quantitative information so long as the absorption constitutes a small portion of the total cavity loss (e.g. the absorption is small compared to losses at the mirrors).

The more detailed response of CRDS to the effects of cavity design and implementation was the subject of much discussion in the early CRDS literature.$^{49–51,78,82,83}$ A ringdown cavity is a high-finesse etalon, and, as such, possesses a discrete mode structure dependent upon the design of the cavity. For a cavity constructed from two spherical surface mirrors of radius $R_1$ and $R_2$ separated by a distance $L$, the frequencies of the stable cavity modes are given by the equation$^{52,84,85}$:

$$u = \frac{c}{2L} \left( n + (1 + m + l) \frac{\cos^{-1} \left( \sqrt{g_1 g_2} \right)}{\pi} \right)$$  \hfill (9)

where $g_1 = 1 - \frac{l}{R_2}$ and $g_2 = 1 - \frac{l}{R_1}$. The parameters $g_1$ and $g_2$ are dimensionless quantities that can be used to determine whether a given cavity design is stable. For a stable cavity, the condition $0 < g_1 g_2 < 1$ must hold. In Equation (9), $n, l,$ and $m$ are integer quantities used to index the modes of the cavity. The parameter $n$ represents the longitudinal mode number and is approximately of the order of $2L/\lambda$, $l$ and $m$ represent the transverse mode numbers. For the lowest order mode, commonly referred to as $TEM_{00}$, $l$ and $m$ are zero. Here, we see that for a cavity constructed from plane parallel mirrors where $R_1$ and $R_2$ are infinite, we recover the well-known frequency transmission of the Fabry–Perot type of etalon

$$u = \frac{nc}{2L}$$  \hfill (10)

The frequency structure of the cavity modes can be visualized as consisting of $TEM_{lm}$ longitudinal modes whose frequency separation is given by Equation (10) as $c/2L$. The frequency space between these $TEM_{lm}$ modes will be filled to a greater or lesser degree by higher order transverse $TEM_{lm}$ modes, depending upon the exact design of the cavity. When a cavity is subjected to excitation by a very narrow-linewidth continuous wave (CW) laser, not all laser frequencies are transmitted
through the cavity. Only those frequencies that correspond to stable modes of the cavity are transmitted. The behavior of such a cavity under pulsed excitation was also the subject of much discussion. Arguments have been presented that the short coherence length of pulsed lasers, in general, precludes mode effects. Other concerns have been expressed that for the absorption features narrower than the mode spacing of the cavity, it is possible that absorption features could be missed (since only light at the mode frequencies rings down in the cavity). In practice, however, for pulsed laser excitation, such effects have not been problematic. Cavities can be easily designed to possess a near continuum of transverse modes. Typical pulsed laser linewidths are also wider than even the normal spacing between the TEM_00 longitudinal modes, so that light from the pulsed laser is injected into the cavity regardless of laser frequency or transverse mode structure. Finally, it has been noted that while mode effects may modulate the total intensity of the signal exiting the cavity, the signal usually never drops to zero. Since the ringdown time and not the intensity is monitored in CRDS, a small modulation does not greatly hinder the ringdown measurement.

3 INSTRUMENTATION

3.1 Ringdown Cavities

A ringdown cavity in its original form consists of two high-reflectivity mirrors with a mirror spacing that meets the stable cavity conditions discussed in the preceding section. Nowadays, a ringdown cavity can have various forms, such as a cavity consisting of more than two high-reflectivity mirrors, a pair of superpolished prisms, a single piece of prism, a section of single-mode optical fiber with two identical fiber Bragg gratings inscribed on it, a fiber loop, or a cavity with a plasma or a flame in it. Although there are many forms of ringdown cavities, the fundamental characteristics remain the same: laser light is trapped in a high-finesse cavity to experience many round trips to enhance the measurement sensitivity. Owing to different geometries and/or different cavity configurations, experimentally observed ringdown times can range from nanoseconds to hundreds of microseconds. Berden demonstrated an extremely short ringdown cavity (3 cm) in 1998. Le Grand and Le Floch reported a very long cavity (270 cm) in 1990. A cavity used to demonstrate a compact acetone detection device was only 13 cm in length (Figure 3), which yielded a ringdown time of 700 ns in the deep ultraviolet (UV) region. For liquid detection, cavity lengths can even be on the order of μm. Conversely, using ultrahigh reflectivity mirrors in the infrared (IR) region, e.g. 99.9985%, a 43-cm cavity had a ringdown time of up to 100 μs and a ringdown time of several hundreds of microseconds has been reported in a fiber loop ringdown system.

Often a mirror-based ringdown cavity can only be used for measurement of a very limited number of species because of the relatively narrow bandwidth of ultrahigh reflectivity mirrors. However, a broadband prism cavity, first introduced by Lehmann and Rabinowitz in 1999, can have a spectral response ranging from the UV to IR. This type of prism cavity can potentially measure spectral fingerprints of various species in different spectral regions. A new type of fiber loop cavity for detection of a small volume of liquid is discussed in Section 7.

3.2 Laser Sources

In principle, there is no restriction on the laser sources to be used for a ringdown system. Both pulsed lasers and CW lasers with wavelengths ranging from the ultraviolet to the IR can be used, given availability of ringdown mirrors coated for the appropriate wavelength region. Commonly employed pulsed lasers include pulsed dye lasers pumped by Nd : YAG or excimer lasers, or widely tunable optical parametric oscillator (OPO) lasers. CW ring dye lasers pumped by Ar^+ lasers and quantum cascade lasers (QCLs) have been also widely used for ringdown studies, as have mid-IR laser sources based on difference frequency generation (DFG) or Raman shifting techniques. Inexpensive telecommunications diode lasers have been increasingly used in ringdown research and instrumentation because of low cost, small footprint, and high resolution. Broadband laser...
sources have also been explored for ringdown studies. Engeln and Meijer injected a broadband dye laser pulse into a ringdown cavity and used a Fourier transform spectrometer to separate the frequency components of the pulse exiting the cavity. Scherer also utilized a broadband laser beam for the development of a ringdown spectrometer. Fiedler et al. measured the C–H overtone of liquid benzene using incoherent broadband CEAS. Perhaps the most nonstandard laser system used for ringdown was reported by Engeln et al., who implemented CRDS in the IR using a free electron laser system to obtain a spectrum of a thin film of C60.

Very recently, a broad-bandwidth optical frequency comb has been coherently coupled to a ringdown cavity and used a Fourier transform spectrometer to separate the frequency components of the pulse exiting the cavity.

A critical issue when employing an absorption spectroscopy method such as CRDS is the laser linewidth. If the laser used in CRDS has a large linewidth, two measurement problems may arise. First, hyperfine structures of an optical transition or an isotopic shift cannot be captured owing to the lack of laser resolution. This is particularly true for atomic transitions and isotopic shift. Second, if the laser linewidth is too broad, accurate measurements for high-resolution spectroscopy and atomic absorption cannot be achieved (mostly, the overall absorption signal can be underestimated). The effects of the laser linewidth on the accuracy of ringdown measurements have been experimentally observed and theoretically analyzed.

Even some pulsed lasers are suitable for moderate to high-resolution spectroscopy. For instance, a pulsed dye laser with double-grating configuration can have a linewidth of 0.08 cm\(^{-1}\) at 590 nm (e.g. NarrowScan) and 0.03 cm\(^{-1}\) at 570 nm (e.g. Sirah). A widely tunable OPO system (e.g. the MOPO-HF), can have a linewidth of 0.075 cm\(^{-1}\). In contrast, CW lasers such as external cavity diode lasers (ECDL) or distributed feedback (DFB) diode lasers typically have a laser linewidth of kilohertz to megahertz levels (1 cm\(^{-1}\) = 30 GHz). Thus, as with other very high resolution absorption spectroscopy methods, CW laser CRDS methods are preferred for very high resolution studies.

Laser beam propagation behavior in a ringdown cavity depends on the cavity geometry and the nature of the medium in the cavity. For example, different gases filling the cavity have different refractive indices, thus generating different scattering losses. Refractive index variations or the existence of a large refraction gradient can increase ringdown baseline noise, create beam steering effects, or even prevent establishment of a ringdown event. For example, beam-steering effects have been observed in a ringdown cavity containing atmospheric-pressure plasma. Severe beam deflections due to gas turbulence have been observed in plasma confined in tubing, preventing the establishment of a ringdown event. A careful design of the ringdown cavity geometry or an optimized plasma gas flow pattern can minimize beam-steering effects.

### 3.3 Electronics

For pulsed-CRDS, the bandwidth of the laser is typically several times larger than the longitudinal mode spacing of the ringdown cavity. Therefore, the light on each laser pulse is coupled into the cavity and no additional electronic parts are required to achieve cavity excitation. When a narrow-linewidth diode laser is used as the light source, an additional electronic control is needed. The linewidth of a diode laser, e.g. an external cavity diode laser or a DFB diode laser, is much narrower than the cavity mode spacing, implying that the laser must be tuned into resonance with a cavity mode in order to excite the cavity. Engeln et al. first reported the use of an intensity-modulated, narrow-linewidth CW ring dye laser for CRDS. This work utilized an unstabilized ringdown cavity and depended upon random fluctuations (such as variations in the cavity length due to vibration) to couple the laser into the cavity modes. To increase the coupling efficiency, a cavity with a dense mode structure was utilized. The phase shift of the intensity-modulated beam exiting the cavity was used to obtain a high-sensitivity spectrum. Later on, Romanini et al. described a method of actively coupling narrow-linewidth CW lasers (such as ring dye and diode lasers). In these experiments, the length of the cavity was dithered by mounting one cavity mirror on a piezoelectric translator. By modulating the length of the cavity, the mode structure of the cavity was swept through the laser frequency. When the laser and cavity mode frequencies overlapped, light was efficiently injected into the cavity mode, rapidly increasing the intensity of the light in the cavity (i.e. the cavity was excited). The schematic of the method is shown in Figure 4. After these initial reports, several early studies using CW-CRDS were reported.

CW-CRDS has matured into a standard ringdown technique. The methods of achieving the cavity excitation can be simply classified into three dominant categories: (i) cavity length modulation to vary the cavity mode spacing, (ii) current modulation to vary the laser frequency, and (iii) a combination of the two
methods. The first and the third methods have been almost abandoned owing to the complexity and the high cost of the required instrumentation. Currently, most instrumentation and research using CW-CRDS implements the current modulation scheme. In CW-CRDS, once the cavity is excited, shutoff of the excitation is needed to observe the ringdown decay behavior. Typically, an acousto-optical modulator (AOM) is used to deflect the laser beam away from the optical axis of the ringdown cavity to shut off the cavity buildup, thus allowing the ringdown waveform to be subsequently recorded. \(^{66-77}\) This method requires an expensive AOM device and a trigger circuit to control the procedure. Another major disadvantage of this method includes a loss of laser power through the AOM. When a laser beam passes through the crystal of an AOM, losses in the observed laser power are typically 15–20\%. This imposes a distinct disadvantage when a low-power DFB diode laser is used as the light source in a CW-CRDS system, since lower signal intensity means lower signal-to-noise ratio. Although many CW-CRDS-based research efforts are still using an AOM, CRDS-based commercial instruments have avoided implementing this device. \(^{15}\)

An alternative approach to shut off the cavity excitation without using an AOM in CW-CRDS is controlling the laser current. Once the cavity is excited, the electrical signal from the detector is used to trigger a circuit, which drives the laser diode current below the threshold of the driving current. This procedure typically requires a specially designed electric circuit. This circuitry is a trivial engineering effort, but it is not readily available for research laboratories. Recently, a simple and effective method has been introduced to achieve cavity excitation and shutoff, using a standard off-the-shelf power combiner. \(^{17,46}\) With this approach, the power combiner couples the output of a function generator with the output of a pulse generator to create a special voltage waveform to manipulate the diode laser current. This eliminates the need to use special electronic modulation circuits to achieve current modulation. This method has been successfully used in several ringdown research studies and applications. \(^{17,46,57,58,62,64,113,114}\)

### 3.4 Data Analysis

Ringdown signals from a PMT or photodiode detector are typically digitized using a digital oscilloscope, transient digitizer, or fast A/D converter interfaced to a computer. Ringdown software is typically in-house developed, but is also commercially available. To determine the ringdown time, the resulting data is fitted as a single exponential function. In practice, averaging of multiple waveforms is often employed to smooth out shot-to-shot variations in the ringdown signals and improve the signal-to-noise ratio. Strictly speaking, such averaging is only valid if the waveforms are normalized in intensity. Alternatively, the ringdown time of each individual transient can be computed, followed by averaging a number of the computed time constants. Some early ringdown experiments used a dual-channel boxcar integrator to compare two different regions of the ringdown signal and extract a quantity proportional to the ringdown time. \(^{115}\) This approach yielded results comparable to data fitting methods. However, the software method has the added advantage of providing a quick method of establishing if the ringdown waveform is a true single exponential decay. It is a simple matter to check the observed ringdown time in different regions of the transient to determine if the waveform is truly a single exponential function. In practice, e.g. if the difference in the ringdown times obtained by fitting different ranges in the decay curve is less than about 1\%, fitting a single exponential decay is justified. Cavity misalignments, linewidth effects, and index of refraction variations in the cavity can all lead to nonexponential or multiple exponential waveforms. \(^{116}\) Scherer et al. have considered, in some detail, the effect of various data-acquisition schemes and have concluded that while the temporal resolution of a digitizer system is important for determining the number of points sampled, the vertical resolution can be critical to the performance of a CRDS system. \(^{70}\)

### 4 MOLECULAR APPLICATIONS OF CAVITY RINGDOWN

#### 4.1 Introduction

At the time of this writing (2007), CRDS and its variants have yielded more than 700 publications worldwide.
(based on a search using SciFinder). Of these publications, the majority are using CRDS in the area of molecular spectroscopy. Whether for fundamental molecular structure studies, or for applications in areas such as environmental monitoring, combustion studies, or plasma processing, CRDS has proven its capability to detect weak molecular absorptions or to measure trace molecular species. Molecular applications of CRDS continue to be one of the most active fields using CRDS. It also is the field that clearly demonstrates the extreme sensitivity of the cavity ringdown technique. A complete review of molecular spectroscopy using CRDS is beyond the scope of this article. However, reviews are available for further information concerning molecular spectroscopy using CRDS.\textsuperscript{69,76,80,117–119}

4.2 Applications

4.2.1 Fundamental Molecular Spectroscopy

The measurement of a doubly forbidden transition in molecular oxygen by O’Keefe and Deacon provided the first demonstration of the ringdown technique.\textsuperscript{1} Since then, molecular spectroscopists have taken advantage of the high sensitivity of CRDS and utilized CRDS in a wide variety of environments. Saykally and coworkers, in one of the earliest studies, demonstrated the usefulness of the technique in supersonic expansion applications by combining CRDS with a pulsed vaporization cluster source to record absorption spectra of Cu\textsubscript{2} and Cu\textsubscript{3} in a supersonic molecular beam.\textsuperscript{120} This same group has continued the application of CRDS to cluster studies, eventually expanding their efforts to include a number of metal and mixed species clusters\textsuperscript{121} as well as water\textsuperscript{95} and methanol\textsuperscript{122} clusters. The ultrasensitivity of CRDS also lends itself naturally to studies of molecular predissociation.\textsuperscript{123–125} Figure 5 depicts a comparison of CRDS and LIF absorption spectra for HNO that clearly reveal features missing in the LIF spectrum due to predissociation of the molecular excited state.\textsuperscript{89} Radical spectroscopy has also been the subject of ringdown studies, as demonstrated by early investigations of OH in flames\textsuperscript{86,123,126,127} and the SH radical in an absorption cell.\textsuperscript{125} Miller’s group have observed weak electronic transitions of large alkoxy radicals in the NIR (1.2–1.3\,\mu m) using CW-CRDS and the radicals are generated by laser photolysis of selected precursors. The absorption cross sections of these transitions are typically only on the order of 10^{-21}\,cm^{-2}. With the high sensitivity of ringdown spectroscopy, abundant rotational and vibrational data have been obtained for methyl peroxy (CH\textsubscript{3}O\textsubscript{2}),\textsuperscript{128} trifluoromethyl peroxy (CF\textsubscript{3}O\textsubscript{2}),\textsuperscript{129} acetyl peroxy (CH\textsubscript{3}C(O)O\textsubscript{2}),\textsuperscript{130} propyl peroxy (C\textsubscript{3}H\textsubscript{7}O\textsubscript{2}),\textsuperscript{131} phenyl peroxy (C\textsubscript{6}H\textsubscript{5}O\textsubscript{2}),\textsuperscript{132} and ethyl peroxy (C\textsubscript{2}H\textsubscript{5}O\textsubscript{2})\textsuperscript{133} radicals, whose spectra in UV or visible (VIS) are typically overlapped so that little spectroscopic information can be obtained. An early demonstration of the extreme sensitivity of

![Figure 5](image-url)  

**Figure 5** Cavity ringdown spectra (a) and LIF (b) of HNO A^1A'–X^1A' transition (100)-(000) K' = 4-K'' = 3 and (020)-(000) K' = 5-K'' = 4 subbands. Line assignments are shown by the combs above the spectra. Much of the structure present in the CRDS spectrum is absent in the LIF spectrum because of predissociation of the A^1A'' state. (From ref. 89. Reproduced by permission of the American Institute of Physics.)
the technique was the observation of weak overtone transitions. Romanini and Lehmann used cavity ringdown to investigate very weak overtone transitions in HCN.$^{(80)}$ In so doing, they demonstrated per pass absorbance detection limits on the order of $10^{-7}$. In addition to molecular structure studies, CRDS has also been used in kinetics experiments.$^{(134–137)}$ By monitoring the temporal densities of chemical reaction products and/or reactants, reaction kinetic constants and reaction mechanisms are investigated.$^{(134–138)}$ It should be noted that fundamental molecular spectroscopic studies using CRDS have been extended beyond the few areas briefly mentioned above and the publications continue to increase.

### 4.2.2 Combustion Flame Chemistry and Plasma Diagnostics

A consistent challenge facing the combustion community has been to measure concentrations for various reactant, intermediate, and product molecules as a function of flame conditions and position within the flame. Direct sampling from such an environment is inaccurate, particularly for radicals, since reactions continue to proceed as the gas is sampled and transferred to an analysis system. The distribution of species in the gas sample may bear little resemblance to the original gas at the sampling position in the flame. Thus, accurate in situ methods for combustion analysis have long been desired. However, the hostile environment and intense background emission of such systems can frustrate attempts to use traditional optical analytical methods for in situ measurements. Emission spectroscopy is only capable of detecting excited state species, greatly limiting its usefulness for diagnostic purposes. Other techniques such as LIF,$^{(117)}$ coherent anti-Stokes Raman spectroscopy (CARS)$^{(139)}$ and degenerate four-wave mixing (DFWM)$^{(117)}$ have all yielded excellent results, but can be hampered by difficulties in calibrating for absolute measurements. A highly sensitive absorption spectroscopy technique, such as CRDS, provides an ideal complement to other analytical diagnostic methods.

The use of CRDS for flame analysis was first reported in 1994 by Meijer et al.$^{(80)}$ This work measured the absolute absorbance for OH radicals (near 308 nm) generated in a Bunsen burner flame. Since that time, a number of CRDS studies have investigated radical concentrations in flames including HCO,$^{(140)}$ CH$_3$,$^{(117)}$ CH$_2$,$^{(141)}$ and CH.$^{(142)}$ Also, studies have continued to investigate the behavior of the OH radical under various combustion conditions.$^{(132,136,126,127,145)}$ Mercier et al. carried out extensive measurements comparing CRDS, direct absorption spectroscopy, and LIF for quantitative analysis of OH radical concentrations and spatial profiles in flames.$^{(143)}$

Zalicki et al. demonstrated the detection of methyl radicals generated when a mixture of methane and hydrogen flowed over a heated filament.$^{(144)}$ Absorbances and spatial profiles were measured for methyl radical column densities far below those required for standard multipass absorption spectroscopy. Schocker et al. measured absolute concentrations of OH, HCO, and CH$_2$ in a propene flame near the soot-formation limit.$^{(145)}$ Both temperature and radical concentration profiles were discussed in that study.

Direct applications of CRDS for detection of species in a plasma have been somewhat more limited in number. However, due to the dual facts that plasma technology is very important in semiconductor industries, material processing, and analytical applications, and that CRDS has the unique capability of measuring absolute concentration of chemical species in plasmas, this number has grown rapidly during the last few years. In a very early development, O’Keefe used the technique to measure N$_2^+$ ions in a glow discharge.$^{(146)}$ Kotterer, Conceicao, and Maier, studied N$_2^+$ ions in a hollow cathode source.$^{(147)}$ Negative ion concentrations were reported by Quandt, et al., who used CRDS for quantitative measurements of H$^-$ ions in a magnetic multipole source.$^{(148,149)}$ In this case, rather than traditional absorption, the optical losses associated with the electron photodetachment process were monitored. Later, Romanini et al. investigated the spectra of naphthalene cations created in a slit jet/electronic discharge source.$^{(150)}$ This work resulted in the first gas-phase electronic spectrum for an ionized polycyclic aromatic hydrocarbon. Wang et al.$^{(151)}$ measured OH density profiles in an atmospheric argon inductively coupled plasma (ICP) using a pulsed-CRDS system. They also measured the density of SrOH radicals in the plasma using an external cavity diode laser at 679 nm.$^{(146)}$ Recently, Oever et al. measured NH and NH$_2$ radicals using CRDS in an extensive characterization of the Ar-NH$_3$ expanding thermal plasma source, which is widely used for silicon nitride deposition in industrial processes.$^{(152)}$

Of perhaps the most practical interest for plasma analysis is the use of CRDS for measurements in reactive plasmas for semiconductor growth and plasmas employed in analytical applications. Monitoring the species present during semiconductor growth can provide important information for controlling the growth process, detecting impurities, and optimizing plasma operation conditions. In related research, Campargue et al. used CRDS to determine the concentrations of SiH$_2$ radicals in a dc discharge plasma containing a mixture of silane and argon.$^{(153)}$ Both, et al. have employed CRDS to measure radicals and etch products in a capacitively coupled radio-frequency plasma.$^{(154)}$ SiF$_2$ was measured as a product of
the etch process when a silicon wafer was placed in the system. Interest in plasma diagnostics using CRDS continues to increase. Key plasma parameters, which include electron density and plasma temperatures, can be characterized through ringdown measurement of species in the plasma. Owing to the large gradients of plasma temperature and heterogeneity of plasmas, plasma temperature profile and electron density profile are spatially dependent. Linewidth broadening mechanisms in plasma, including Doppler broadening, Stark broadening, and collisional broadening, are complicated. Which mechanism is dominant under a particular plasma condition is dependent on the plasma temperature(s), electron density, location in the plasma, etc. Detailed discussions on linewidth broadening mechanisms under plasma conditions can be found elsewhere. A recent review on plasma diagnostics using laser techniques including CRDS was given by Ganguly et al. Yarlin et al. measured the spatial profiles of \( \text{N}_2^+ \) concentration in an atmospheric pressure N \text{ glow discharge} by CRDS. They also measured the temporally resolved \( \text{N}_2^+ \) concentration in a pulsed atmospheric pressure N plasma. Wang et al. measured concentration and lineshapes of atomic lead transitions at 283 nm in different vertical and lateral positions of an atmospheric argon ICP. Fitting a lineshape into a Voigt lineshape yields Doppler and Lorentzian components, from which plasma gas kinetic temperature and electron density were estimated. In this way, a plasma gas kinetic temperature profile and electron density profile in the plasma were mapped out. Using similar method, the lineshapes of the rotational transition line \( S_{21}(1) \) in the OH \( A^2 \Sigma^+ \rightarrow \chi^2 \Pi \) (0–0) band were measured and plasma kinetic temperature profile was also derived. Through simultaneous measurements of ringdown absorption spectra and emission spectra of OH radicals in the plasma, the local thermoequilibrium approximation (LTE) was evaluated. One disadvantage of the ringdown measurement in a circular plasma is the line-of-sight measurement, which yields an integrated measurement along the laser beam path. Although Abel inversion can convert the line-of-sight measurements to radial distributions, the conversion process requires a relatively large number of data points in order to achieve an accurate measurement. However, practically, this line-of-sight measurement gives an acceptable measurement uncertainty of plasma gas temperature and electron density, e.g. 10–15%, for plasma diagnostics.

Another relatively new CRDS-related application is sputtering plasma monitoring. Ion beam sputtering plasma is created when an energetic ion beam bombards the surface of a metallic target. In the process, chemical species, such as small molecules, free radicals, and atoms are sputtered from the target and form a sputtering plasma. Real-time in situ monitoring of sputter erosion is important in the operation of electric propulsion devices and the development of nuclear magnetic fusion. Compared with other optical techniques that are used for sputtering monitoring, such as optical emission spectrometry (OES), LIF, and resonance-enhanced multiphoton ionization time-of-flight mass spectrometry (REMPI-TOF-MS), CRDS is advantageous in the areas of real-time response, high sensitivity, and absolute measurement of number densities. In an earlier work, CRDS was used to measure the number density of silicon (Si) atoms generated by radio discharge plasma sputtering. Recently, CRDS has been used to study sputter erosion of a metallic target. In those studies, the ion beam source and the target were housed in a vacuum chamber with a background pressure of \( 10^{-6} - 10^{-7} \) Torr. Energetic argon ions bombarded a metallic target and elements were generated around the surface of the target. CRDS with a UV laser beam (375–400 nm) from an OPO system was used to detect the densities of the sputtered elements, such as iron (Fe), aluminum (Al), molybdenum (Mo), and titanium (Ti). Detection sensitivities of these elements were in the \( 10^{6} - 10^{7} \) atoms/cm\(^3\) levels, which were lower than typical number densities of sputtered particles in electric propulsion devices. The analytical applications of CRDS associated with a plasma source are discussed in Section 5.

4.2.3 Environmental Applications

Trace chemical detection in environmental applications is another important area in which CRDS is playing an increasingly important role. Soon after the publication of the original CRDS paper, O’Keefe and Lee reported the detection of NO\(_3\) at subpart per billion levels using CRDS in 2002, measured NO\(_3\) using narrowband pulsed dye lasers and Ball in 2003, also measured NO\(_3\) using a broadband pulsed dye laser. Mazurenka et al. demonstrated fast Fourier transform cavity ringdown spectroscopy (FFT-CRDS) for detection of NO\(_2\) with a detection sensitivity of 150 ppt. Simpson developed a CW-CRDS spectrometer to monitor NO\(_3\) and NO\(_2\) at 662 nm with a detection limit of 2.4 ppt for NO\(_2\) in a 25-s average. Meijer’s research group demonstrated the detection of NH\(_3\) at the 10 ppb level, and a detection limit of less than 1 ppt was reported for mercury in room air.

Results such as the above have sparked a keen interest in the use of CRDS for difficult environmental monitoring problems. Vasudev et al. explored the use of CRDS for applications in monitoring offgases from
thermal treatment systems such as hazardous waste incinerators.\textsuperscript{(29)} The real-time detection of low vapor pressure chlorinated organic species, and in particular species such as the dioxins and furans, is highly desirable and extremely difficult. Other ultrasensitive techniques such as LIF and REMPI suffer a reduction in sensitivity for such species due to a strong intersystem crossing between excited state singlet and triplet levels. CRDS, being an absorption method, is much less affected by the fate of the excited state and should possess the sensitivity to implement such measurements. The Orr-Ewing research group reported measurements of trace volatile organic compounds (VOCs), such as ethyne, ethene, 1,3-butadiene, 1-buteni-2ne, 2-methylpropene using two DFB lasers and one ECDL in the NIR.\textsuperscript{(171)} The detection limits of these VOCs are in the subparts per billion to a few parts per million levels. The same group combined a preconcentration technique typically used in gas chromatography (GC) with CW-CRDS and demonstrated the capability of measuring ethane in urban air at a mixture ratio level of 6 ppb.\textsuperscript{(172)} Winstead et al. measured absorption cross sections of the first C–H overtone of several VOCs, such as benzene, toluene, chlorobenzene, and dichlorobenzene using an NIR external cavity diode lasers cavity ringdown spectroscopy (ECDL-CRDS) system.\textsuperscript{(173,174)} More recently, Cias reported measurement of absorption cross sections of the first C–H overtone of 1,3-butadiene, 2-methyl-1,3-butadiene (isoprene), and 2,3-dimethyl-1,3-butadiene using CW-CRDS at 1650 nm.\textsuperscript{(113)} The overlap of the overtone spectra of many large VOCs challenges the spectral selectivity. One possible solution is to measure the fundamental transition in the middle IR using an IR laser source.

With the increasing concern about global warming and more stringent standards for reduction of the greenhouse gas (CO\textsubscript{2} and CH\textsubscript{4}) emissions, interest in measurement and monitoring of atmospheric greenhouse gases remains high. CRDS is receiving growing recognition of being able to play an important role in this field. For example, the use of CRDS as an intelligent control system for advanced coal combustion system to monitor typical emission gases (e.g. CO\textsubscript{2}, CO, NO, NO\textsubscript{2}, N\textsubscript{2}O, SO\textsubscript{2}) together with total mercury.\textsuperscript{(175)} Early measurements of important atmospheric/environmental molecules, such as CO\textsubscript{2}, NH\textsubscript{3}, CH\textsubscript{4}, and HCHO were performed in a laboratory low-pressure system. Fawcett reported the first measurement of tropospheric methane using CW-CRDS at 1650 nm with a detection limit of 52 ppb.\textsuperscript{(31)} Awtry and Miller developed sensors for air quality monitoring in spacecraft capsules using CW-CRDS at 1550 nm.\textsuperscript{(32)} They demonstrated detection limits for CO and CO\textsubscript{2} at single digit parts per million levels and for NH\textsubscript{3}, HCN, and C\textsubscript{2}H\textsubscript{2} at a few parts per billion levels. Similar atmospheric molecules, such as, CO, CH\textsubscript{4}, NH\textsubscript{3}, and C\textsubscript{2}H\textsubscript{2}, were also measured by CRDS’s variant, CEAS or ICOS in the early studies.\textsuperscript{(176)}

One of the important applications in greenhouse gas monitoring is to identify the source of greenhouse gases. The isotopic abundance ratio of C\textsubscript{13} to C\textsubscript{12} is a reliable signature for source identification. Diode laser CRDS offers a high-resolution and high-sensitivity measurement of the C\textsubscript{13} isotope. Crosson et al. developed a sensitive NIR CW-CRDS system for measurement of the isotopic ratio of C\textsubscript{13} to C\textsubscript{12} in the range of 6261–6264 cm\textsuperscript{-1}.\textsuperscript{(154)} The low-pressure measurement at 70 Torr yields a high accuracy of 0.22 ppm, which is comparable with the results obtained using isotope ratio mass spectroscopy (IRMS). Castrillo et al. also developed a spectrometer for measurement of C\textsubscript{13}/C\textsubscript{12} in CO\textsubscript{2} at 0.25 μm.\textsuperscript{(177)} The instrument has an accuracy of 0.5 ppm for C\textsubscript{13}. Wang et al. recently developed a battery-powered, remotely accessible, portable ringdown spectrometer for detection of CO\textsubscript{2}, CH\textsubscript{4}, and C\textsubscript{13}.\textsuperscript{(114)} The instrument is being tested at the US Department of Energy carbon sequestration sites. Two laser diodes at 1650 and 1596 nm were multiplexed through a fiber splitter for simultaneous measurements of CO\textsubscript{2}, CH\textsubscript{4}, and C\textsubscript{13} in two different wavelength regions. Ding et al. combined 31 DFB laser diodes to measure absorption spectra of C\textsubscript{13} in the 6130–6750 cm\textsuperscript{-1} and numerous new transitions were added to the CO\textsubscript{2} spectral database.\textsuperscript{(178)} ICOS and DFG-based IR absorption have also been used to measure C\textsubscript{13} isotope in the IR spectral regions. Owing to the larger line strength of the fundamental transition in the IR,\textsuperscript{(179)} these methods have also achieved high sensitivity.

Recently, CRDS has been employed for studies of optical extinction by aerosol particles. CRDS measures the total optical extinction resulting from the sum of scattering and absorption losses.\textsuperscript{(190,180–182)} The losses depend on the number density, size distribution, and index of refraction of the particles. Different laser sources including UV and NIR laser have been used to measure extinction caused by particles such as nonabsorbing polymer beads and absorbing smoke particles. Thompson et al. investigated the extinction coefficient of ambient air as a sensitive indicator of micrometer-sized airborne particles through CRDS at two wavelengths.\textsuperscript{(183)} Very recently, Timothy et al. demonstrated the measurement of single aerosol particle extinction using optical feedback cavity ringdown spectroscopy (OF-CRDS) method.\textsuperscript{(184,185)} The OF-CRDS technique allows high repetition rate measurement up to 1.25 KHz, which allows multiple measurements of the aerosol extinction of a single particle.
5 ATOMIC APPLICATIONS OF CAVITY RINGDOWN SPECTROSCOPY

5.1 Introduction

Application of CRDS for atomic absorption measurements was first reported by Jongma et al.\(^{(101)}\) who reported measurement of elemental mercury in air using CRDS with a detection limit of less than 1 ppt. Subsequently, Miller and Winstead\(^{(18)}\) demonstrated the first P-CRDS measurements for analytical atomic spectrometry by introducing an ICP source into a CRDS system and measuring lead concentrations using a pulsed laser at 283 nm. In analytical P-CRDS, the plasma is used as an atomization source to generate atoms and ions and CRDS serves as a sensitive detector. Several publications have reported continuing development of analytical P-CRDS. P-CRDS has been demonstrated to be a powerful technique not only for high-sensitivity analysis of a variety of elements but also for trace isotopic measurements. During the last 10 years, several elements and isotopes have been measured using the P-CRDS technique. The use of different plasma and laser sources has been demonstrated and detection limits comparable to inductively coupled plasma mass spectrometry (ICP-MS) have been reported. A review of P-CRDS for elemental and isotopic measurements has recently been published.\(^{(21,77)}\) This section incorporates an update on the development of the P-CRDS technique since the last review. Emphasis is placed on the improvement of the P-CRDS technique and isotopic measurements.

5.2 Principle of Plasma Cavity Ringdown Spectroscopy

P-CRDS follows the same measurement principles as CRDS. Including losses resulting from the high-temperature atmospheric plasma and the open-air cavity, the observed ringdown time in a P-CRDS system can be expressed as\(^{(20)}\) in Equation (11):

\[
\tau = \frac{d}{c(1 - R + \beta_{\text{plasma}}l_s + \beta_{\text{air}}(d - l_s) + \text{absorbance})}
\]  

(11)

where the absorbance is defined in Equation (5). In the case of plasmas, the density of absorbers is position dependent. As a result of the complicated linewidth broadening mechanisms under atmospheric plasma conditions, the lineshape of the absorption line is of a Voigt profile and the absorption cross section can be represented by Equation (13)\(^{(52,106)}:\)

\[
\sigma_{ij}(v) = \frac{g_j}{g_i} \frac{\lambda^4}{4\pi^2c} \frac{A_{ji}}{\text{V}(a, 0)\sqrt{\pi \ln 2}}
\]  

(13)

where \(g_j\) and \(g_i\) are the upper and lower state degeneracies respectively, \(\lambda\) is the transition wavelength, \(c\) is the speed of light, and \(A_{ji}\) is the spontaneous emission transition rate (also known as transition strength or transition Einstein A coefficient). For most atomic/ionic transitions, these parameters are well documented in the literature. \(\Delta\lambda_D\) is the Gaussian component of the broadened linewidth due to Doppler broadening. \(V(a, 0)\) is the Voigt function determined by linewidth broadening mechanisms and the \(a\) parameter is determined by the ratio of Lorentzian and Gaussian components.\(^{(157)}\) In practice, the measured lineshape is typically the spatially averaged and integrated lineshape along the particular line of sight; therefore, an averaged value of the cross section is obtained.

Using the experimental lineshape data to determine the average cross section allows for the measurement of the average density of atoms or ions in the lower state of the transition to be probed. For the purpose of plasma diagnostics, such as measuring the distribution profile of electron density, gas kinetic temperature, and analyte/species density, the line-of-sight measurement may generate a large deviation.\(^{(20,151,155,187,188)}\) Abel inversion may be used to convert the lateral measurements to the radial distributions.\(^{(20,189)}\) However, for analytical applications in which the detection sensitivity is the quantity of concern, the line-of-sight measurement is appropriate.

5.3 Plasma Cavity Ringdown Spectroscopy for Elemental Measurements

5.3.1 Inductively Coupled Plasma Cavity Ringdown Spectroscopy

The ICP is a robust plasma source and has widely been used as an excitation source for emission spectroscopy study of analytes. Miller and Winstead first coupled an inductively coupled plasma cavity ringdown spectroscopy (ICP-CRDS) to demonstrate general analytical atomic applications of CRDS.\(^{(18)}\) The ICP-CRDS system was initially constructed using a pulsed laser source and an ICP source to demonstrate the technical feasibility.
and to explore the detection sensitivity of the system. A standard lead (Pb) solution was diluted at different concentrations and injected into an ultrasonic nebulizer to generate sample gas mist, which was carried by argon into an atmospheric-pressure argon ICP. The plasma used a standard ICP quartz torch coupled with a 27.12 MHz ICP power supply. The detection limit of Pb at 283-nm transition line was in the microgram per microliter level. Figure 6 shows the first elemental measurement of Pb using the ICP-CRDS technique. Following the initial introduction of ICP-CRDS, extensive P-CRDS optimization has been investigated by optimizing each operating parameter individually and, subsequently, in combination with the other parameters. The detection limit of the system has been improved to 300 pg mL\(^{-1}\) for Pb, which is several orders of magnitude lower than the initially demonstrated detection limit. This detection limit of Pb is much better than the detection limit obtained by ICP-OES, slightly better than inductively coupled plasma laser-induced fluorescence (ICP-LIF), and comparable with that from ICP-MS. It should be noted that the results in that work were obtained with a modified ICP plasma torch, which allowed the ICP to operate at an extremely low power of 200 W. With this modified ICP-CRDS system, Pb, Hg, and Mn were also measured and the detection limits were in the nanogram per microliter to picogram per microliter levels.

5.3.2 Microwave Induced Plasma Cavity Ringdown Spectroscopy

The measurement of Pb by the low-power ICP-CRDS system inspired the exploration into different plasma sources, especially those capable of operating at low plasma powers. Microwave induced plasma (MIP) is a powerful alternative source for atomic excitation in elemental analysis and has been extensively used in analytical atomic spectrometry. Compared with other types of plasma sources, an MIP offers some attractive characteristics, such as low power, low gas flow rates, and low cost for instrumentation and maintenance, making it a desirable source for absorption measurements. Duan et al. have investigated coupling an microwave induced plasma cavity ringdown spectroscopy (MIP-CRDS). In that study, lead was chosen as a typical element for the system demonstration so that the results could be directly compared to those from an ICP-CRDS system. A detection limit of 0.8 ng mL\(^{-1}\) for Pb was obtained in that initial feasibility study.

Physically, an MIP-CRDS system has a smaller instrument footprint, lower weight, and lower operating costs than an ICP-CRDS system. MIP-CRDS also has one unique analytical merit that is not offered by ICP-CRDS: the baseline noise, \(\sigma/\tau\), is not affected by the presence of the plasma. In the ICP-CRDS system, the ringdown baseline noise was three to four times larger when the plasma was on than when the plasma was off. However, it was found that the MIP used in the MIP-CRDS system did not generate additional baseline noise to the system. Whether the plasma was on or off had no effect on the baseline noise, which was the same at about 0.3% in both on and off conditions. These results indicate that the baseline noise is improved by a factor of 3–4 by using an MIP in place of an ICP. It should be noted that in addition to the plasma associated baseline noise, the laser beam position in the plasma and the plasma gas flow rates also influence the detection sensitivity. Very recently, a low-power miniature microwave plasma torch (MPT) has been employed with CRDS to measure elemental mercury with a plasma operating power of only 15 W.

Diode lasers have also been employed for atomic spectrometry in P-CRDS. An external cavity diode laser operating at 679 nm was used to measure strontium (Sr). In that study, diluted standard solutions of strontium (Sr) were introduced into the plasma by an in-house fabricated sampling device combined with an ultrasonic nebulizer. \(\text{SrOH radicals}^{193–195}\) were generated in the plasma, and the detection of Sr was made by measuring \(\text{SrOH radicals}^{193–195}\) in the plasma. This study demonstrated the potential of P-CRDS instrumentation using a compact CW laser source.

5.4 Plasma Cavity Ringdown Spectroscopy for Isotopic Measurements

Isotopic analysis is an important field in analytic atomic spectroscopy. For example, in the field of environmental monitoring, isotopic abundance is often
used as spectral fingerprint to study transform, fate, and chemical processes of analytes. Most isotopic analyses are performed by a laboratory ICP-MS system. However, these systems require tedious sample preparation and sophisticated operation and maintenance, and they are not portable for real-time, on-site analysis. The ICP-MS system can also suffer from isobaric effects. For instance, an ICP-MS system cannot readily distinguish $^{238}\text{U}$ from $^{238}\text{Pu}$. In early studies, an ICP was combined with the LIF technique (ICP-LIF) to measure U isotopes at 286 nm. Uranium has a strong transition at 286 nm and the isotopic shift is of 0.6 cm$^{-1}$.

With the ICP-LIF technique, the measurements of $^{235}\text{U}$ and $^{238}\text{U}$ in different matrices were conducted with a detection limit of 1 µg mL$^{-1}$.

LIF combined with laser ablation was also implemented to measure isotope ratios of $^{235}\text{U}$ transition at 682.67 nm and $^{238}\text{U}$ at 682.69 nm under low-pressure conditions and achieved a detection limit of 0.6 µg mL$^{-1}$.

The ICP-CRDS system was applied to isotopic measurements of uranium at three different wavelengths: 286, 358, and 409 nm. The U transitions at 286 and 409 nm are ionic transitions, but the U transition at 358 nm is an atomic transition. With the optimized ICP-CRDS system, the detection limits of U and its isotopes were in the nanogram per microliter levels. This research demonstrated high-resolution isotopic analysis with high detection sensitivity using the P-CRDS technique.

The Hg transition at 254 nm has seven stable isotopic components with well-documented abundance ratios. An early ICP-CRDS system was used to measure a low-resolution hyperfine contour of this transition. The isotopic abundance ratio of the stable isotopic components was barely quantified. The linewidth broadening under the high-temperature ICP ultimately limited the instrument’s capability of measuring high-resolution hyperfine structures of the Hg transition at 254 nm. With the lower plasma temperature in the MIP, the Hg hyperfine structures were more clearly resolved. With a newly developed tube-shaped MIP torch (MPT), which allowed the plasma to operate at powers as low as 15 W, high-resolution Hg hyperfine structures were also recorded as shown in Figure 8.

When the three different plasma sources (ICP, MIP, and MPT) were applied to the P-CRDS system for Hg measurements, interesting spectral background information was obtained. With the ICP-CRDS system, no significant spectral interference was observed. However,
with the MIP-CRDS system, a strong OH transition located at 253.65 nm generated a significant spectral interference with the absorption peak of Hg at 254 nm. This OH transition was attributed to the overlap of two broadened rovibrational transitions $R_{21}(21)$ and $P_{1}(15)$ of the OH A-X (3–0) band. The spectral interference limited the detection sensitivity of the Hg. This OH interference observed when using the MIP was remarkably eliminated by using a tube-shaped MIP torch, which was constructed in a long quartz tube. The disappearance of the OH-spectral interference in the microwave plasma torch cavity ringdown spectroscopy (MPT-CRDS) is partially due to the fact that the MPT has a very small cross-sectional area at the end of the tube interacting with the plasma surroundings.

5.5 Electrothermal Atomization Cavity Ringdown Spectroscopy

An atomization technique that would also appear to lend itself well to CRDS is electrothermal atomization (ETA). As with other conventional absorption techniques, electrothermal atomization atomic absorption spectroscopy (ETA-AAS) attempts to measure a small change in the total transmitted intensity of a light source through an absorbing medium. For a commercial ETA-AAS system, the typical absorbance detection may approach $10^{-4}$ at best. Comparing this value to the $10^{-5} – 10^{-8}$ absorbance for CRDS, the potential of coupling the two techniques together is obvious. An estimate of potential electrothermal atomization cavity ringdown spectroscopy (ETA-CRDS) performance can be obtained by comparison with modern commercial ETA-AAS systems, where a Pb characteristic mass of approximately 5 pg is typical. The characteristic mass implies an absorbance of $4.4 \times 10^{-3}$. By again assuming an approximately $10^{-5}$ absorbance detection and scaling the mass linearly with the absorbance, the CRDS detection limit is expected to be in tens of femtogram range.

Winstead, Miller, et al. successfully demonstrated the first use of ETA-CRDS for measurement of elemental mercury. The introduction of the graphite furnace within the cavity requires simply that the furnace be stable and that the laser beam pass through the center of the graphite tube. In this initial study, the furnace housing windows were removed to reduce optical loss and small holes at the ends of the graphite furnace were introduced to pass the laser beam. Some evidence of the presence of oxygen within the system, especially at high temperatures, was noted. Mounting the mirrors directly on the furnace housing with an argon gas purge would eliminate this problem. Once again, the primary loss mechanisms governing the decay time of the cavity are mirror reflectivity losses, atomic absorption in the graphite furnace, plus Rayleigh scattering from air in the cavity. As CRDS is based on measuring an intensity decay rate, it discriminates effectively against the furnace blackbody radiation.

Owing to the transient nature of the atomic absorption signal in a graphite furnace, a fast, high-resolution data-acquisition system is required so that integrated absorbance values can be obtained for each atomization cycle. The PMT signal was digitized by a 12-bit, 100 MHz sample rate analog-to-digital converter with the timing for data acquisition determined by the software controlling the graphite furnace. Eighty waveforms were saved over a period of 4 s for each atomization cycle, from which the peak and integrated absorbance values were determined. Figure 9 depicts the response of $1/\tau$ for lead (283 nm) as a function of the data-acquisition time following the start of the atomization step. Using a system having effective mirror reflectivity of 99.86% and a baseline ringdown time variation of 2–3% yielded detection limits of 1 and 2.7 pg for lead and mercury, respectively. These results are an order of magnitude better for mercury, but only slightly better for lead, than the typical detection limit obtained by ETA-AAS. Additional enhancements can come from further optimization of the laser linewidth, increased cavity stability during the furnace atomization sequence, a faster duty cycle for data acquisition, and optimization of the furnace operation itself. For example, the atomization process within a graphite furnace is generally complete in under 1 s while an Nd : YAG laser repetition rate is only 10–100 Hz (20 Hz in the example above). This implies that significant benefit would accrue from the use of higher repetition rate lasers.

![Figure 9](image_url)  
**Figure 9** Analytical shape of lead atomization peak obtained from cavity ringdown time measurements by injecting 7.5 µl of 2 ng ml$^{-1}$ lead standard solution for each heating cycle. (From ref. 19. Reproduced by permission of The Royal Society of Chemistry.)
Recent work has focused on developing a CRDS mercury emission monitor. Such an instrument requires, among other things, a determination and elimination of any background absorptions or interferences caused by other constituents of flue gas emissions from coal-fired power plants. For example, it is well known that sulfur dioxide (SO₂) absorbs UV radiation in the same spectral region as mercury (253 nm) resulting in a significant problem for most mercury detection equipment. Indeed, presently used commercial Continuous Emission Monitors (CEMs) based on atomic emission, atomic fluorescence, or atomic absorption require the removal of SO₂, and other flue gas constituents, before an accurate determination of the mercury concentration can be made. Recent research using CRDS to monitor mercury emissions from coal-powered utilities used thermal decomposition to convert mercury compounds to elemental mercury to provide a total mercury measurement. It has been noted that the presence of isotopic structure during a scan of the mercury 253-nm line raised the possibility of separating these two absorbance components. Using a diode-seeded alexandrite laser, this possibility was confirmed. That is, the characteristic Hg isotopic peaks could be used to provide a unique identifier for mercury in exhaust gases. For example, using a gas mixture containing 1.2 ppb mercury and 2175 ppm SO₂ respectively, the five mercury peaks obtained using CRDS are easily resolved above the SO₂ background absorption, and it was possible to accurately extract both the Hg and SO₂ concentrations. In 2004, Miller performed a field test of this instrument at a Department of Energy (DOE) Pittsburgh facility. The results obtained support the conclusion that CRDS is a very promising technique for monitoring total mercury. However, practical success of such instruments dependent on the development of compact and low-cost UV laser sources remains a challenge.

6 MEDICAL APPLICATION OF CRDS–BREATH ANALYSIS

6.1 Introduction

Normal human breath contains hundreds of VOCs in very low concentrations ranging from part per trillion to part per billion levels. Some VOCs have been identified as biomarkers for specific diseases. For instance, alkanes are present in the case of lung cancer and formaldehyde in the case of breast cancer; the presence of isoprene in human breath is related to blood cholesterol levels; and patients with Type 1 diabetes (T1D) or on ketogenic diets have acetone in their breath. Such knowledge suggests that breath analysis is useful for human disease diagnostics. However, owing to the low concentration and the large number of chemical species in exhaled breath, breath analysis requires highly sensitive and selective instruments to detect and identify the abnormal concentrations of specific biomarkers. One major instrument presently employed for breath VOCs analysis is gas chromatograph mass spectrometry (GC-MS).

Owing to its unique features of high sensitivity and absolute measurement of gas concentration of species of interest, CRDS has been well recognized to be an excellent technique for real-time, noninvasive breath gas analysis. However, its application in breath gas analysis is still in its infancy. At the time of this article being written, there have been only a few publications reporting on breath analysis using CRDS or using its variant – cavity leak-out spectroscopy (CALOS) or using its variant – cavity leak-out spectroscopy (CALOS). However, the application of CRDS to breath analysis is expected to increase. Recent reviews on breath analysis are available.

6.2 Breath Analysis

Monitoring of C13 isotopic ratio in breath gas can help diagnose the presence of bacterium *Helicobacter pylori*. Crosson et al. measured carbon isotopic ratio of C13 to C12 in breath CO₂ using CW-CRDS in the NIR spectral region. For the original form of CRDS, this is likely the first report on medical application of CRDS. They used a DFB laser diode at 1657 nm and performed measurements at low pressure (70 Torr). The detection limit of δ C13 was 0.22 per mil and was compared with the results from a commercial isotopic spectrometer. Wahl et al. reported recent progress on C13 isotope measurement using CW-CRDS, also in the NIR spectral region. Using a preconcentration process, they demonstrated the capability of measuring the C13 isotope in both high-concentration CO₂ (e.g. 4%) and low-concentration CO₂ (e.g. 350 ppm) with an accuracy of 0.2 per mil. Wang et al. developed a compact ringdown device using a miniature 266-nm laser source for detection of acetone, a biomarker of diabetes in breath. The instrument has sufficient detection sensitivity to detect abnormal breath acetone. The instrument was further improved and evaluated in the areas of detection sensitivity and response time with acetone sample solutions. They demonstrated that a single measurement of acetone can be done within 46 s using the prototype acetone breath analyzer. The detection limit of acetone was 0.49 ppm. Very recently, this acetone detection device has been reconfigured to be a portable unit and tested with 59 human subjects including type 1 and type 2 diabetic outpatients in a clinic.

Instead of using CRDS, several studies on breath biomarkers using the CRDS variants CALOS, CEAS,
and ICOS, have been reported. Ethane and pentane in human breath gas are biomarkers for lipid peroxidation and oxidative damage of human tissue. Murtz et al.\textsuperscript{215} first reported on the measurement of breath ethane and pentane using mid-IR CALOS. The detection limit of ethane is 100 ppt. The same group also demonstrated on-line monitoring of breath ethane using the CALOS at 3.3 μm\textsuperscript{216} which was generated by periodically poled lithium niobate (PPLN) pumped by an Nd:YAG laser. The detection sensitivity was later improved to 6 ppt by using a mid-IR OPO laser source, and multiple breath compounds in human breath gas such as methane, ethane, and water were simultaneously analyzed.\textsuperscript{217} Halmer et al.\textsuperscript{225} recently reported on a mid-IR CALOS spectrometer and demonstrated the detection of breath carbonyl sulfide (OCS) with a detection limit of 7 ppt. In that study, multiple species in a single breath, such as ethane, CO\textsubscript{2}, and O\textsubscript{2} were simultaneously measured. The temporal resolution of the breath-ethane concentration was clearly resolved within the first 500 s. In comparison, the GC method used in that research required 30–60 min for a measurement and the CALOS needed less than 1 min, as shown in Figure 10. The method demonstrated in this work is expected to be extended to the analysis of other small molecules such as NO, CO, OCS, and other hydrocarbons. Bakhirkin et al.\textsuperscript{226} have demonstrated an ICOS-based system using a QCL at 5.2 μm to measure breath NO for diagnostics of lung disease. Very recently, McCurdy et al. have demonstrated real-time simultaneous measurement of NO and CO\textsubscript{2} in a single breath cycle using ICOS with two QCLs operating at 5.45 and 5.22 μm. They demonstrated the detection limit of NO at 0.4 ppb with a 1 s integration time.\textsuperscript{227}

The Ye research group has recently introduced a novel cavity-based technique for analysis of multiple breath species in a broad spectral range. They reported human breath analysis using an optical frequency comb fiber laser combined with CEAS over a range of 200 nm in the NIR. The measured mixture gas includes CO, CO\textsubscript{2}, CH\textsubscript{4}, H\textsubscript{2}O, and NH\textsubscript{3}.\textsuperscript{228}

Human breath gas analysis dates back to more than three decades ago. However, real-time, on-line breath gas analysis has been made possible only recently by CRDS or its variants, CALOS, CEAS, and ICOS. The promising application of CRDS in breath analysis for disease diagnostics and metabolic status monitoring can be seen in recent reviews and related publications.\textsuperscript{56, 219–221, 227, 229} A current challenge in breath analysis using CRDS and its variants is to eliminate the spectral interference from many other species present in human breath. To address this issue requires more studies on the spectral fingerprints of human breath compounds. Breath gas analysis by CRDS is in its infancy, but we believe that this will be one of the fastest growing areas of CRDS application. Ringdown breath analyzers are expected to become a commercial reality and replace the time-consuming, expensive, and nonportable GC-MS for point-of-care (POC) breath analysis in some situations in the near future.

7 FIBER LOOP RINGDOWN TECHNIQUES

7.1 Introduction

One of the essential characteristics of CRDS is enhanced detection afforded by the long path/multiple interaction approach. This feature has been recently implemented by
using a “conceptual cavity” – a fiber loop formed by a section of single-mode fiber, thus being generally referred to as fiber loop ringdown.\( ^{91}\) This method is modeled after the ringdown concept. However, a conceptually new approach is used, eliminating dependence on an ultrahigh reflectivity cavity. This new fiber ringdown technique utilizes an optical resonator – an optical fiber loop – as the ringdown “cavity”. Light is coupled into the fiber loop; and when the light source is rapidly shut off, the resultant light rings down inside the fiber loop for many round trips. In each round trip, a small fraction of light leaks to a photodetector through a fiber coupler; and the remaining light rings in the fiber experience internal fiber transmission losses. The signal intensity observed by the detector follows an exponential decay. The lower the losses of the light in the fiber, the longer the decay time constant (ringdown time). When an external action, such as an absorption or evanescent wavefield interaction is applied to a small section of the fiber, the observed ringdown time decreases. This type of fiber ringdown technique functionally resembles the standard high-reflectivity CRDS for absorbance measurements, but without the requirements of high-reflectivity parts.

### 7.2 Fiber Loop Ringdown Chemical Sensors

Culshaw et al. first introduced an optical fiber loop with a length of several tens of meters with a 5-cm open path microoptical gas cell for gas-phase absorption measurement.\( ^{91}\) Figure 11 shows a schematic of the fiber loop ringdown system. Owing to the large insertion loss from the gas cell, an additional Erbium-doped fiber loop was included in the fiber loop to operate just below the threshold for net amplification of the light in the loop. Owing to the excessive optical loss of the laser power in the sensor head (the cell) and large optical insertion losses in the fiber connection/coupling points in the fiber loop, the device showed a short ringdown time, \(\sim 100\) ns and poor detection sensitivity. On the basis of the same instrument scheme, the same group recently demonstrated an improved version of the device, which yielded ringdown times of up to hundreds of microseconds.\( ^{94}\) Loock’s group reported on a simplified fiber loop ringdown technique by introducing a micro air gap into a section of fiber in the fiber loop for detection of a small volume of dye solutions.\( ^{6,230}\) They demonstrated the measurement of \(7 \times 10^{-15}\) mol dye solution using both a CW laser and a pulsed laser. In this study, the laser pulse was coupled into the fiber loop through a direct illumination of a bend in the fiber loop and the detection of the laser pulse leaking out of the fiber was achieved through another bend in the fiber loop. The same group further advanced the fiber loop ringdown technique by introducing phase-shift measurement, which greatly improved the data-acquisition rate to close to real time \((10–100\) ms).\( ^{60}\) This technique has been demonstrated to be suitable for low-cost, real-time, and on-line detection of capillary electrophoresis with a detection limit at micromolar concentration levels. Using flow injections, the device can detect a series of solution samples at different concentrations. The demonstrated detection limit is \(5.3 \times 10^{-12}\) mol sample in a 530 p-liter volume.\( ^{231}\) Very recently, a minimum fractional absorption of \(6\) cm\(^{-1}\) has been demonstrated by using the fiber loop ringdown technique with a fast gain switch diode laser.\( ^{232}\) In an early publication, Tarsa et al. reported their study on an optical fiber resonator for CRDS, in which the sensor head was made of a section of tapered fiber in the loop and evanescent field absorption was detected.\( ^{5,59}\) A small volume of liquid sample was detected by this type of fiber loop ringdown technique. They also demonstrated the detection of a single-cell adsorption event.\( ^{61}\) Vogler et al. developed a similar fiber loop ringdown device and demonstrated measurement of the diffusion coefficient of hydrogen on silicon through monitoring the OH absorption in the NIR region.\( ^{233}\)

### 7.3 Fiber Loop Ringdown Physical Sensors

In addition to chemical sensor development using the fiber loop ringdown technique, physical sensors using the fiber loop ringdown concept have been recently demonstrated. Wang and Scherrer extended the fiber loop ringdown

![Figure 11 Schematic of a typical fiber loop ringdown experimental system. (Reproduced from ref. 91 by permission of IOP Publishing Ltd.)](image-url)
technique for development of low-cost, fast-response, and large-measuring-range pressure sensors.\(^{57,58,234}\) A section of bare single-mode fiber with a length of 1 cm was used as the sensor head. The sensing principle is primarily based on the fact that micromechanical deformation of the fiber drastically increases optical loss in the fiber loop.\(^{235}\) The sensor showed repeatable response to pressure, as shown in Figure 12. By using a different baffle layer outside of the bare fiber, different sensing ranges of pressure and/or force can be achieved by the fiber loop ringdown pressure/force sensor. This technique can be further developed for detection and monitoring of mechanical fatigue of materials in an inaccessible and/or harsh environments.

Using a similar fiber loop ringdown approach, Wang and Mbi introduced an optical fiber Bragg grating loop for temperature sensor development.\(^{62,65,236}\) The Bragg wavelength is temperature dependent. Change of the temperature in the sensor head fiber Bragg grating (FBG) shifts the relative position of the laser wavelength in the FBG wavelength-dependent bandwidth curve, and thus the temperature change results in different transmission rates of the laser beam through the FBG. Different optical losses due to the shift of the FBG curve resulting from the temperature change in the FBG are detected by measuring the ringdown time. One advantage of the fiber FBG loop ringdown temperature sensors is high temperature accuracy. In that work,\(^{65}\) an accuracy of 0.06 °C was demonstrated in the temperature range of 45–78 °C. Another advantage of the FBG loop ringdown temperature sensor is the low cost compared with the current FBG-optical spectral analyzer (FBG-OSA) temperature sensor. In the FBG loop ringdown temperature sensor, an inexpensive photodiode replaces the expensive optical spectral analyzer (OSA) as the detector. A detailed discussion on the advantages and disadvantages of the FBG loop ringdown temperature sensors compared with the FBG-OSA temperature sensors can be found elsewhere.\(^{65}\) A schematic of fiber grating loop ringdown sensor is shown in Figure 13.

By using a long period grating (LPG) as the sensor head, the fiber grating loop ringdown temperature sensor demonstrated a large temperature measuring range, from −169 to 950 °C.\(^{62,65}\) More recently, a double loop dual sensor head configuration has been developed for multiple location sensing.\(^{237}\) Using high-temperature composite fiber materials to fabricate a sensor head, such as an FBG or an LPG, high-temperature, fast-response,
low-cost, fiber grating loop ringdown temperature sensors can be developed for a variety of applications in harsh environments.

8 RINGDOWN INSTRUMENTS

It has been two decades since the first publication of the CRDS technique. Although CRDS has become a mature technique, manufacturing and sale of commercial ringdown instruments for a nonresearch market is a relatively recent event. Owing to the intrinsic nature of the ringdown approach, (e.g. extreme sensitivity to optical and mechanical stability) transitioning the CRDS technique from a research laboratory to a commercial reality is a significant science and engineering achievement. This stride was first successfully made by scientists and engineers at Tiger Optics in 2002 \(^{(238)}\) with the introduction of a moisture analyzer, the MTO-1000-H2O. A product line (e.g., H2O, CH4, and O2 ringdown analyzers and tracers) has been subsequently created. Instruments for measuring low concentrations of water and methane in high-purity semiconductor manufacturing gases or in specialty gases are being distributed all over the world. In addition to engineering challenges, a common challenge in ringdown instrumentation is to reduce the instrument cost. Cost is mainly determined by the price of laser sources and high-reflectivity mirrors. Laser cost may not be an issue for instrumentation using inexpensive telecommunications diode lasers; however, for an instrument needing a UV laser source, the availability of compact and low-cost UV laser sources remains a challenge. The effect of mirror cost is diminished when mass production of a ringdown product is implemented. Coating 40 identical high-reflectivity mirrors at a specific wavelength does not cost much more than coating one pair.

9 PERSPECTIVE AND FUTURE DEVELOPMENTS

During the last two decades, CRDS has experienced a full technological cycle, from the introduction of the concept, laboratory fundamental research, to full commercialization of the ringdown instrument. CRDS has had a relatively short cycle through the invention–development–commercialization process. From the analytical spectroscopy point of view, CRDS has brought about a revolutionary change in terms of ultrahigh sensitivity, simplicity, and absolute measurement of trace chemical species in close to real time. The development of this powerful analytical technique coincides with the rapid expansion of new semiconductor materials and telecommunications technologies, which promote rapid advancement of new laser sources and optical fiber components, such as compact, inexpensive, fiber pigtailed laser diodes. The new generation of laser sources, optical coating/polishing technologies, and advanced fiber components allows for continued aggressive development of ringdown instrumentation and applications. CRDS has been demonstrated for trace analysis, environmental monitoring, material processes, medical applications, remote sensing, etc. CRDS has been extensively used to study and detect gas-phase species, and its applications in liquid detection are being aggressively pursued. Theoretical considerations for a total internal reflection ring cavity for thin films and liquids were investigated by Pipino et al. in the early days of CRDS development. \(^{(2,239)}\) Engeln et al. have also demonstrated the spectroscopy of thin films by inserting a coated optical flat into a standard ringdown cavity. \(^{(100)}\) Loock’s group demonstrated promising real-time analytical applications in microfluids using the fiber loop ringdown technique. \(^{(63)}\) The detection of a single-cell absorption event represents a start of the ringdown applications in a new field. \(^{(61)}\) Snyder and Zare first demonstrated the novel combination of CRDS with high-performance liquid chromatography (HPLC) in 2003. \(^{(245)}\) They designed a flow cell with wedged angles that minimized optical losses through all cell surfaces at Brewster’s angle; this flow cell was coupled to the output of an HPLC separation for the detection of separated analytes by their absorption properties using CRDS with a pulsed laser. The technique has been extended to use a CW laser and has demonstrated the potential of liquid-phase CW-CRDS to be used as an absorption detector for HPLC measurements. \(^{(25)}\) Very recently, Sneppen et al. have demonstrated liquid chromatography (LC)–CRDS using an OPO system to achieve measurements in UV region. \(^{(240)}\) Being a powerful measurement technique, the technology associated with the ringdown concept is sure to continue to find new areas of application, such as security screening, food safety inspection, plenary exploration, clean energy study, disease diagnostics, and remote sensing.

1 Introduction

Infrared emission spectroscopy (IRES) is a branch of experimental infrared (IR) spectroscopy that can be considered as an alternative to the more commonly used IR absorption or reflection techniques for observing vibrational transitions in molecular systems. While these methods provide spectral data that are similar regarding their information content (structural, analytical), IRES may have definite advantages (or drawbacks) depending on the object to be studied.

This article aims at giving an up-to-date account of the theory, instrumentation and laboratory practice of IRES. Following an introduction to the principles and nature of thermal radiation, the governing laws of IRES are outlined and analyzed in some depth, with the aim of defining the conditions for obtaining analytically meaningful IR emission spectra. Spectral distortions concomitant with the measurement of condensed-phase samples and other sources of error are pointed out along with the procedures devised for their elimination. Various methods of excitation of thermal radiation and the instrumentation most often used in laboratory measurements of IR emission spectra are described, with emphasis on modern Fourier transform (FT) techniques and with an outlook to special applications like remote sensing and process monitoring. Attention is given to data manipulation and presentation of emission spectra in relation to quantitative evaluation of spectral data. Recent advances in sample handling techniques, for example allowing the measurement of optically thick samples or thin surface layers, are also reviewed, while reference is given to the original sources of literature in the field.

1 INTRODUCTION

IRES is concerned with the analysis of energy distribution, as a function of frequency (wavenumber) or wavelength, of the electromagnetic radiation emitted by objects (samples) in the IR spectral region. The IR region of the electromagnetic spectrum is usually considered to be from 4000 to 400 cm\(^{-1}\) (2.5 to 250 µm), or including also the near-infrared (NIR) and far-infrared (FIR) regions – from 14 000 to 10 cm\(^{-1}\) (0.7–1000 µm). Emission encountered in this spectral region is associated with vibrational, vibrational-rotational or pure rotational motions of molecules. Since these quantized motions may be more or less excited at temperatures higher than absolute zero (0 K = \(–273.15^\circ\)C = \(–459.67^\circ\)F), their relaxation leads to emission of thermal (mostly IR) radiation. Thermal excitation is the most common excitation mechanism of IR emission of gases, liquids and solids, and we will focus here on spectroscopic aspects of this phenomenon. Other excitation mechanisms such as chemiluminescence or photoluminescence will not be dealt with in detail as they are governed by somewhat different laws.

IR emission spectra of various objects can be continuous or discontinuous. The spectral distribution of energy in the continuous (or blackbody-like) emission spectra are characteristic only of the temperature of the emitter, while discontinuous spectra containing narrow emission bands or lines are characteristic of its material properties as...
The goal of IR emission spectroscopic measurement is the same as that of IR spectroscopy in general: to get an insight, through the observable spectral features of the objects, into the chemical composition, molecular structure, configuration and conformation of the molecules, the nature of chemical bonding and intermolecular interactions within the sample. If the spectral features can be assigned to known chemical species, the measured emission spectral data can be utilized in qualitative or quantitative analysis, in much the same way as in the more commonly used infrared absorption spectroscopy (IRAS). Depending on the samples and conditions of measurement (temperature, physical state, energy conditions) one or the other IR spectroscopic observation technique may be preferred. A special topic of IRES of great theoretical interest is the investigation of highly excited vibrational and vibrational-rotational states, not conveniently accessible to absorption studies.

In laboratory practice, the instruments used for the measurement of IR emission spectra are essentially the same as those used in IRAS, with a difference in sample arrangement: in IRES the emitting sample replaces the standard light source or it is put in an optically equivalent position (often in an auxiliary sample compartment outside the instrument cover). In principle, any type of IR spectrometer is capable of measuring IR emission spectra, but since the radiation to be detected may be rather weak (when the sample temperature is relatively low), high-performance FT (interferometric) spectrometers are preferred to dispersive instruments owing to their higher optical throughput and other known advantages leading to higher sensitivity.

Thus, a typical Fourier transform infrared (FTIR) instrument used for the measurement of IR emission spectra consists of an emission port (receiving the radiation from the auxiliary emission accessory), a modulator (interferometer) and a broad-range IR detector. The IR radiation emitted by the sample enters the interferometer in the form of a collimated beam where it gets modulated, then is focused on the detector. The analog signal of the interferogram is measured at equidistant data points and is converted to digital data, by means of an analog-to-digital converter (ADC). As a rule, the interferogram is measured repeatedly many times and the data are accumulated (averaged) to increase the signal-to-noise ratio (S/N). The so-called single-beam emission spectrum (the energy spectrum) is obtained from the interferogram via Fourier transformation by means of a PC or dedicated microcomputer. Double-beam emittance spectra (corresponding to transmittance spectra in absorption spectroscopy) are obtained by ratioing the single-beam emission spectrum of the sample to that of a laboratory blackbody, used as reference, measured under the same conditions (same temperature) as the sample.

The applicability and potentials of IRES as a method of measurement to solve analytical problems must be considered in comparison with those of IR absorption and reflection techniques. One of the main advantages of IRES stems from its single-ended measurement geometry, which means that the sample need not be put inside the instrument: it should be accessible only from one side or is seen from a distance. This makes IRES one of the basic methods for remote sensing, e.g. of natural sources of thermal radiation such as hot gases, and explains its widespread application in environmental, atmospheric, extraterrestrial or astrophysical research. The same applies to in situ measurements for process control, e.g. in the chemical industry. In laboratory conditions IRES is preferred when very hot or chemically aggressive samples have to be examined which cannot be or would be risky to place into the sample compartment of a spectrometer. The IR emission technique is equally applicable to smooth and rough surfaces, and can be used with transparent and nontransparent substrates such as metals. Thin overlayers on metal surfaces (e.g. lubricants on moving machine parts) are ideal samples for IRES without any sample preparation, and chemisorbed molecules on metal single crystal surfaces can be detected even at monomolecular coverage when using special detection techniques.

The principal drawback to IRES is that for IR emission to occur, a molecule must go from an excited vibrational state back to the ground state; and in order to have a detectable flux of such radiation, there must be a significant proportion of molecules in the excited state. To achieve such a population of vibrational modes whose transitions are observed in the mid-IR region, the sample must be heated, which may not only be inconvenient but also injurious to many substances, especially those of organic origin. A further difficulty is introduced by background emission: the emission of the hot surroundings of the sample, which may overwhelm the signal from the sample of interest. Thus, for practical applications of IRES, a restricting condition is that during measurement the sample must be kept at a constant temperature differing from that of the spectrometer (detector).

Furthermore, with condensed-phase samples, IRES is limited to the examination of thin layers not exceeding a few micrometers in thickness – just as in transmission. Measurement of the surfaces of much thicker samples or thin overlayers on top of opaque substrates is not a simple task; it requires special sample handling methods such as transient heating or cooling to obtain meaningful emission spectra. Since IR emission is often accompanied by undesirable absorption and reflection phenomena and heat transfer that may disturb the observation or distort the emission spectrum, a good understanding of the
underlying laws and principles is needed to set up the right measurement conditions.

Several earlier reviews on IRES are available in the literature reflecting the state of the art and the field of interest of the time of their publication. Our presentation will necessarily overlap with these, while illuminating some new topics of present-day interest.

2 THEORETICAL BACKGROUND

2.1 Basic Terms and Principles

2.1.1 Infrared Radiation

Just like visible light, IR radiation is part of the spectrum of electromagnetic waves. At the same time it may also be considered as consisting of massless energy parcels called photons. In fact, both descriptions are needed to account for all radiative and optical phenomena that have been observed.

An electromagnetic wave may be identified by its wavelength ($\lambda$), frequency ($\nu$), or wavenumber ($\tilde{\nu}$). These three quantities are related to each other through Equation (1):

$$\tilde{\nu} = \frac{\nu}{c} = \frac{1}{\lambda}$$

where $c$ is known as the speed of light (actually, it refers to the velocity of all kinds of electromagnetic radiation); in vacuum $c = c_0 = 2.99792458 \times 10^8$ m s$^{-1}$. Note that the speed of light depends on the medium in which the wave travels, and may be related to the speed of light in vacuum, $c_0$, by Equation (2):

$$c = \frac{c_0}{n}$$

where $n$ is the refractive index of the medium. By definition, the refractive index of vacuum is unity ($n = 1$), while for any other media it is greater: for most gases it is very close to 1 (for air $n = 1.0003$ in the visible part of the spectrum), but most dielectric media have $n$ values as great as 1.4 to 4.

The wavelength, $\lambda$ (expressed in $\mu$m = $10^{-6}$ m), is a quantity that can be measured experimentally (e.g. with an interferometer). The wavelength scale was introduced in spectroscopy in 1868 and has been used since, mainly in the ultraviolet (UV) and visible regions. The frequency, $\nu$, is defined as the number of waves that pass a given point in one second (measured in cycles/s = s$^{-1}$ = Hz). However, in the IR region it is more practical to divide the actual frequency value with the speed of light and replace it with the much smaller value obtained, the wavenumber, $\tilde{\nu}$, which gives the number of waves in one centimeter of vacuum, leading to its units as cm$^{-1}$. It is this spectral variable and measurement unit that are almost exclusively used in IR spectroscopy (although the wavenumber values are often referred to as “frequencies” in the spectroscopists’ slang).

An electromagnetic wave or photon carries with itself an amount of energy, $E$, proportional to its frequency, (Equation 3):

$$E = h\nu = h\tilde{\nu}$$

where $h = 6.62608 \times 10^{-34}$ J s is known as the Planck constant. The unit of energy most often used in connection with photons or electromagnetic waves is the electron volt, eV ($1$ eV $= 1.6022 \times 10^{-19}$ J). The energy of the photon is conserved as light passes from one medium to another, which means that the frequency of light does not change at the interface. Note, however, that in accordance with Equations (1) and (2), wavelengths and wavenumbers do change when light enters another medium with a different refractive index. (However, in everyday applications of spectroscopy this dependence is generally neglected, i.e. wavenumber values pertaining to vacuum are used.)

The arrangement and limiting values of the different regions of the electromagnetic wave spectrum are shown in Figure 1 in terms of the above mentioned scales. The terms IR emission and thermal radiation are often used as synonyms; in fact, thermal radiation, defined as electromagnetic waves that are emitted by a medium owing solely to its temperature, may extend from IR through the visible spectrum into the near UV region in case of very hot emitters (e.g. incandescent light sources, or the sun).

2.1.2 Principles of Thermal Radiation

All media continuously emit electromagnetic radiation, randomly in all directions, depending on their
temperature and on the properties of their material. Radiation emitted by a homogeneous medium is also homogeneous, unpolarized and isotropic. Before discussing the quantitative laws of thermal radiation that are fundamental to IR emission spectroscopy of gases, liquids and solids, a general acquaintance with the nature of thermal radiation and thermal equilibrium may be appropriate.

Any emission of IR or thermal radiation is concomitant with some loss of energy of the emitter. Since objects at a temperature of absolute zero (0 K) are at their lowest possible energy level, they are obviously unable to emit any energy in that state. But at higher temperatures a certain proportion of molecules are rotationally and vibrationally excited (electronic excitation takes place at much higher than room temperature), and these molecules spontaneously emit energy in the form of thermal radiation while relaxing to lower-lying energy levels. At the same time the surrounding molecules or objects may absorb some of the emitted photons and get excited. Thus there is a continuous radiative exchange of energy leading to redistribution and equalization of temperature within a thermally isolated system.

Let us consider an evacuated enclosure with totally reflecting inner walls, thermally isolated from the outside, containing two objects of similar mass and different temperature. In accordance with the general experience, the two objects will, in time, have the same temperature. Since heat conduction and convection is excluded in vacuum, the only interaction between the two objects is thermal radiation. As was discovered at the beginning of the 19th century (C. Prévost, 1809), any object emits energy depending on its own temperature, irrespective of the temperature of the surroundings. Thus in our example the hotter object initially emits more energy than it absorbs and gets cooler, while the cooler object absorbs more energy than it emits and gets warmer, until thermal equilibrium sets in. At thermal equilibrium the objects emit just as much radiant energy per second as they absorb, thus there is also radiation equilibrium, i.e. a uniform radiation field inside the enclosure.

The outcome of our fictional experiment will be the same if one of the objects in the isolated enclosure is absolutely black throughout the spectrum (usually referred to as blackbody) and the other is not. But since the blackbody absorbs all radiation falling on it, at thermal equilibrium it must also emit the same amount of energy. The other object may absorb less (and reflect or transmit the rest) but then it will also emit less than the black object. By this reasoning we discover a one-to-one correspondence between absorptance ($\alpha$) and emittance ($\epsilon$) of an object, an important law discussed in more detail in section 2.3.

2.1.3 Radiant Energy

The radiation field is characterized by its radiant energy density, $H$, defined in Equation (4) as

$$H = \frac{Q}{V}$$

where $Q$ is the total radiant energy and $V$ is the volume. The radiation field is composed of radiation of various frequencies or wavelengths, which can be represented by Equation (5):

$$H = \int_{0}^{\infty} H_v \times d\nu = \int_{0}^{\infty} H_\lambda \times d\lambda$$

where $H_v$, $H_\lambda$, and $H$ are the spectral radiant energy densities expressed in terms of frequency, wavenumber and wavelength, respectively. (“Spectral” in these terms indicates that the radiant energy density is a function of the actual spectral variable, and is considered within the spectral intervals ($v$, $v + dv$), ($\tilde{v}$, $\tilde{v} + d\tilde{v}$) or ($\lambda$, $\lambda + d\lambda$) respectively.)

2.1.4 Energy Levels, Transitions and Emission Probability

The total energy of a molecular system is composed of the energy of electronic, vibrational and rotational motions and, according to quantum theory, it can assume discrete values depending on quantum numbers that specify the level of excitation of each type of motion. Any absorption or emission of IR radiation is associated with transitions between vibrational or vibrational-rotational energy levels (Figure 2), whereas the amount of energy absorbed or released, $\Delta E$, is proportional to the frequency, $v$, or wavenumber, $\tilde{v}$, of the radiation (Equation 6):

$$\Delta E = E_j - E_i = hv = hc \tilde{v}$$

Figure 2 Energy levels in the potential energy curve of a diatomic molecule; arrows drawn with full line signify absorption, arrows with dotted lines signify emission.
where $E_i$ is the energy of the upper level, $E_j$ is that of the lower level. Transition from a higher to a lower energy state (designated as $E_j \rightarrow E_i$) is accompanied by emission of energy, while transition from lower to higher energy states ($E_i \rightarrow E_j$) is concomitant with absorption of energy. The energy levels and transitions between them are often characterized, instead of the energies, by the so-called term values obtained when both sides of Equation (6) are divided by $hc$, leading to quantities given in units of cm$^{-1}$. The frequent use of Equation (6) justifies that in IR spectroscopy priority is given to the wavenumber scale and the cm$^{-1}$ units.

A molecule consisting of $N$ atoms has, in general, $3N - 6$ vibrational degrees of freedom. Depending on the atomic masses, the geometrical arrangement of atoms within the molecule and the forces acting between them, an equal number of so-called normal vibrations will be formed, each of them having a well-defined fundamental vibrational frequency, $v_k$, associated with a specific form or mode of vibration, and a series of quantized energy levels. According to the theory of molecular vibrations, the atomic masses, the geometrical arrangement of atoms, and the vibrational energy of the system is at its minimum. However, at higher temperatures, when the molecules are in thermal equilibrium with their surroundings, a certain portion of them is always at thermally excited vibrational and rotational levels (excitation of electronic energy takes place at much higher temperatures than normal room temperature).

The excited molecules spontaneously emit energy in the form of electromagnetic radiation. The intensity of an emission line belonging to transition $j \rightarrow i$, defined as the amount of energy emitted by the sample per second, is determined by Equation (7):

$$I_{ij} = N_i \hbar c \tilde{v} A_{ij}$$  

where $N_i$ is the number of molecules in the excited state $j$, and $A_{ij}$ is the transition probability (also known as the Einstein coefficient of spontaneous emission). The population of an excited state, $N_j$, relative to that of the initial (lower) state, $N_i$, as a function of temperature is governed by Boltzmann statistics (Equation 8):

$$\frac{N_j}{N_i} = \exp \left(\frac{-(E_j - E_i)}{kT}\right) = \exp \left(\frac{hc \tilde{v}}{kT}\right)$$

where $k = 1.380658 \times 10^{-23}$ J K$^{-1}$ is the Boltzmann constant and $T$ is the absolute temperature. Thus the fraction of excited molecules decays exponentially with the excitation energy but increases with temperature. For instance, at 300 K for a vibration at 200 cm$^{-1}$ the value of $N_j/N_i$ is expected to be 0.38, while for a 1000 cm$^{-1}$ vibration it is only 0.0008; at 500 K these values become about 0.56 and 0.06, respectively. The transition probability of spontaneous emission is defined as the fraction of molecules undergoing transition from the excited state $j$ to the lower state $i$ per second, and can be calculated as in Equation (9):

$$A_{ij} = \frac{64\pi^4 \tilde{v}^3}{3\hbar} |\hat{M}_{ij}|^2$$

where the transition moment (roughly: the change of the electric dipole moment vector, $\hat{M}$, during the vibrational or rotational transition), $\hat{M}_{ij} = \int \psi_i^* \hat{M} \psi_j \mathrm{d}r$, with $\psi_i$ and $\psi_j$ being the eigenfunctions of the initial and final states, respectively, and $\hat{M}$ the electric dipole moment operator.

The above relations provide the general theoretical basis for prediction of band intensities in the emission spectrum. It has been recognized, however, that the limiting values of these intensities are those obtained for an absolute blackbody, and it is more practical to relate the emission spectrum of a sample to that of the blackbody.

### 2.2 The Laws of Blackbody Radiation

#### 2.2.1 Stefan–Boltzmann Law

Much of the early classical research on thermal radiation was devoted to the search for the correct form of the spectral radiant energy density of blackbody, $H_\nu$, as a function of frequency (or wavelength) and temperature. But before that problem could be solved, the temperature dependence of the total radiant energy density of the radiation emitted by a blackbody, $H$, was established by Stefan experimentally (1878) and confirmed by Boltzmann theoretically (1884). The relation they obtained is known as the Stefan–Boltzmann law (Equation 10):

$$H = \sigma \times T^4$$

with $\sigma = 2\pi^5k^4/15c^2h^3 = 5.6705 \times 10^{-8}$ W m$^{-2}$ K$^{-4}$ being the Stefan–Boltzmann constant (where $k = 1.380658 \times 10^{-23}$ J K$^{-1}$ is the Boltzmann constant).

#### 2.2.2 Wien’s Displacement Law

Two partially successful approximations to the spectral distribution of the blackbody radiation were published around the end of the 19th century, the Rayleigh–Jeans law, acceptable only for low frequencies, and Wien’s radiation law, quite accurate for the high-frequency region; now they are only of historical value. Another empirical law discovered prior to the right form of the blackbody radiation function is Wien’s displacement law.
(Equation 11) relating the frequency of the maximum of blackbody radiation to the absolute temperature:

\[ \tilde{v}_{\text{max}} = \text{const} \times T \]  

(11)

2.2.3 The Planck Function

The correct analytical form of the spectral distribution of blackbody radiation was found by M. Planck in 1900 as an interpolation formula between the above-mentioned two approximations; soon afterwards he established his finding theoretically as well by extending Boltzmann statistics with the quantization condition for the emitted energy. The distribution function he obtained this way had integrated in itself all radiation laws established earlier and is known as Planck’s law of blackbody radiation or the Planck function. It is also in agreement with all observed data. The actual form of the Planck function depends on whether it is expressed in terms of frequency, wavenumber or wavelength. In the frequency representation (Equation 12), the density of radiant energy emitted from a unit area of the blackbody source per solid angle in spectral element \( d\tilde{v} \) is:

\[ H_{\tilde{v}}(T) d\tilde{v} = \frac{2hc^{-2} \tilde{v}^3}{e^{hc\tilde{v}/kT} - 1} d\tilde{v} \]  

(12)

(Variations of the Planck function containing a factor of \( 8\pi \) instead of 2 in the above equation refer to radiance considered in the whole solid angle.)

The wavenumber and wavelength representations can be obtained from Equation (12) through Equation (13):

\[ \nu = \tilde{c} = \frac{c}{\lambda} \quad \text{and} \quad d\nu = c \, d\tilde{\nu} = -\frac{c}{\lambda^2} d\lambda \]  

(13)

and using the equivalence of the three representations expressed in Equation (5), to give Equations (14) and (15):

\[ H_{\tilde{\nu}}(T) d\tilde{\nu} = \frac{2hc^2 \tilde{\nu}^3}{e^{hc\tilde{\nu}/kT} - 1} d\tilde{\nu} \]  

(14)

and

\[ H_{\lambda}(T) d\lambda = \frac{2hc^2}{\lambda^5 (e^{hc/\lambda kT} - 1)} d\lambda \]  

(15)

It is customary to introduce the so-called first and second radiation constants, \( C_1 \) and \( C_2 \), having the values given in Equations (16) and (17):

\[ C_1 = 2hc^2 = 1.1911 \times 10^{-12} \text{ J cm}^2 \text{s}^{-1} \]  

(16)

and

\[ C_2 = \frac{hc}{k} = 1.4388 \text{ cm K} \]  

(17)

and write the Planck function in the wavenumber representation simply as Equation (18):

\[ H_{\tilde{\nu}}(T) = \frac{C_1 \tilde{\nu}^3}{e^{C_1 \tilde{\nu}/kT} - 1} \]  

(18)

which is more practical to use when only the relative energy distribution is important (\( C_1 \) may be adjusted to fit the actual application).

Note that Equations (12) and (14) are the same within a constant factor, while Equation (15) describes curves of essentially different shapes, with their maxima shifted considerably toward higher wavenumbers. Thus there are two basically different representations of the Planck function, as shown in Figure 3 (in the same linear wavenumber scale, for three different temperatures). Correspondingly, also Wien’s displacement law (Equation 11) has two versions, Equations (19) and (20):

\[ \tilde{v}_{\text{max}}[\text{cm}^{-1}] = 1.93 \times T[\text{K}] \]  

(19)

for Equation (10), and

\[ \lambda_{\text{max}}[\text{cm}] = \frac{0.283}{T[\text{K}]} \]  

(20)

for Equation (15), and these relations give different maxima for the same temperatures. One has to have a clear idea which of these forms are to be used when applied to IR emission spectroscopy. Seeking the connection with the measurement of blackbody emission spectra, the curves shown in Figure 3 in full line (wavenumber version, Equation 14) can be obtained if the spectrum is scanned with a spectral slit constant in wavenumber (or frequency), while those shown in broken line would be obtained if the spectrum were

Figure 3 Theoretical blackbody radiation curves (Planck functions) for three different temperatures in the wavenumber representation (full lines) and in the wavelength representation (broken lines).
scanned with a spectral slit constant in wavelength. Since modern interferometric (FT) IR spectrometers yield spectra with constant resolution in the wavenumber scale in the whole working region, it is imperative that with FTIR instruments the wavenumber version of the Planck function be used (i.e. Equation 14 or 18) whenever a theoretical blackbody reference spectrum is needed.

Another pitfall that should be avoided when theoretical and experimental blackbody emission spectra are compared (e.g. in order to determine the emitter’s temperature or to find the instrument response function) is to assume that all radiation collected is also detected by the instrument. From the principles of thermal radiation we know that the detector (which is supposed to be as nearly a blackbody as possible) also emits thermal radiation at temperatures higher than absolute zero. Since IR detectors can respond only to deviations from radiation equilibrium, the detector does not ‘see’ all radiation falling on it, only the difference of the blackbody-like emissions from the sample and from the detector (no matter which of them is at higher temperature). Thus, if a room-temperature detector is used and the sample temperature is not very high, the measured spectrum is related to the difference of the corresponding Planck functions. This is illustrated in Figure 4.

### 2.3 Thermal Radiation of Nonblackbodies

When a monochromatic beam of light of unit intensity falls on a slab of condensed-phase material (see Figure 5a), it is divided into three fractions: one may be reflected off the surface, another is absorbed inside the layer and the remainder is transmitted, so that (if scattering and luminescence are neglected) these three fractions add up to unity (Equation 21):

$$\alpha + \rho + \tau = 1$$

where \(\alpha\), \(\rho\) and \(\tau\) are known as the absorptance (or absorption factor), reflectance (reflection factor) and transmittance (transmission factor) of the sample, respectively. (The same quantities are sometimes erroneously

![Figure 5 Schematics of (a) irradiation of a semitransparent slab, and (b) observation of emission by a supported slab.](image-url)
called absorptivity, reflectivity and transmissivity in the literature. The terms with the ending -ance refer to properties of a body (with a given composition, shape, etc.), while the terms with the ending -ivity should refer to properties of a substance measured under standard conditions.)

By definition, a blackbody absorbs all radiation falling on it, thus the absorptance of a blackbody is unity at all frequencies, (Equations 22–24):

\[ \alpha = 1 \quad \text{and} \quad \rho = \tau = 0 \]  
(22)

At another extreme, for a shiny, reflecting metal surface

\[ \rho \approx 1 \quad \text{and} \quad \alpha \approx \tau \approx 0 \]  
(23)

while for an ideal spectroscopic window material

\[ \tau \approx 1 \quad \text{and} \quad \alpha \approx \rho \approx 0 \]  
(24)

However, for most of the common materials, \( \alpha, \rho \) and \( \tau \) are not only between 0 and 1 but strongly wavenumber-dependent as well. They may have narrow absorption lines or broader absorption bands at specific frequencies, and the reflectance may also change in the vicinity of the peaks of strong absorption bands. Those objects for which \( \alpha, \rho \) and \( \tau \) have intermediate values between 0 and 1 throughout the whole spectrum are called graybodies. The ideal laboratory blackbody does not exist; blackbody samples used in emission measurements as reference are, in fact, graybodies that have absorptance or emittance above 0.90 (some may come close to 0.99) in a very broad spectral interval.

2.3.1 Kirchhoff’s Law

One of the basic principles of IRES is the principle of equivalence of absorptance and emittance (discovered by G.W. Kirchhoff in 1860). In its original form Kirchhoff’s law (Equation 25) states that the ratio of the spectral luminance (or radiant flux) of any sample, \( L_s \), at a given temperature, \( T_s \), to its absorptance, \( \alpha_s(\bar{\nu}) \), equals the luminance of the blackbody, \( L_{bb} \), at the same temperature.

\[ \frac{L_s(\bar{\nu}, T_s)}{\alpha_s(\bar{\nu})} = L_{bb}(\bar{\nu}, T_s) \]  
(25)

which implies that \( \alpha_{bb} = 1 \). At the same time the emittance of a sample, \( \varepsilon_s(\bar{\nu}) \), is defined (Equation 26) as the ratio of the radiant flux emitted by the sample \( (L_s) \) to the flux emitted by a blackbody \( (L_{bb}) \) at the same temperature:

\[ \varepsilon_s(\bar{\nu}) = \frac{L_s(\bar{\nu}, T_s)}{L_{bb}(\bar{\nu}, T_s)} \]  
(26)

\( L_s \) may be regarded as the observed luminance of the sample or, as it is often referred to, its single-beam emission spectrum (see also section 2.4). Comparison of Equations (25) and (26) yields Equation (27):

\[ \varepsilon_s(\bar{\nu}) \equiv \varepsilon_s(\bar{\nu}) \]  
(27)

which is the essence of Kirchhoff’s law.

According to this, if a sample absorbs light of a certain frequency, it will also emit at the same frequency. Moreover, this relation means that not only the frequencies but also the so-called selection rules that determine the band intensities will be the same for absorption and emission processes involving the same energy levels of the molecule.

Thus, substituting emittance for absorptance in Equation (21) one gets the basic relation of optical emission spectroscopy (Equation 28):

\[ \varepsilon(\bar{\nu}) + \rho(\bar{\nu}) + \tau(\bar{\nu}) = 1 \]  
(28)

This relation has to be taken into account when choosing the materials for building an emission cell or when interpreting IR emission spectra of condensed materials.

2.4 Practical Aspects of Theory

It follows from Equations (22) and (27) that a blackbody (with \( \alpha = 1 \)) is an ideal emitter (Equation 29):

\[ \varepsilon_{bb} = 1 \quad \text{and} \quad \rho_{bb} = \tau_{bb} = 0 \]  
(29)

Since these conditions are valid for all parts of the spectrum, no material can emit more energy at any given frequency and at any given temperature than a blackbody.

For other types of materials with properties described by Equations (23) and (24) analogous relations can be obtained by substituting emittance for absorptance. Thus, a shiny metal surface is a very poor emitter (\( \varepsilon = \alpha \approx 0 \)), so it makes an excellent back-plate for the sample. In contrast, IR-transmitting cell windows are rarely used as back-plates in IRES since they transmit background radiation.

Nonblackbodies or graybodies in general have emittance in the range of 0 to 1, which changes with wavenumber (Equation 30).

An opaque body’s transmittance is zero (\( \tau_{op} = 0 \)) but its reflectance may be significant in some spectral regions (\( \rho(\bar{\nu}) \neq 0 \)), therefore (Equation 31):

\[ \varepsilon_{op}(\bar{\nu}) = \rho_{op}(\bar{\nu}) = 1 - \rho(\bar{\nu}) \]  
(31)
In molecular spectroscopy one is usually interested in internal properties of the sample, when surface effects may be neglected \((\rho \approx 0)\); in this case (Equation 32):

\[
\epsilon(\tilde{\nu}) \approx 1 - \tau(\tilde{\nu})
\]  

which shows the complementary nature of transmittance and emittance spectra. The spectra in Figure 6 illustrate this relation: the emittance spectrum of a PMMA film on an Al foil (Figure 6c) was obtained by ratioing the single-beam emission spectrum of the sample (Figure 6a) to that of a blackbody reference (Figure 6b); the transmittance spectrum shown for comparison (Figure 6d) was measured in reflection–transmission mode.

2.4.1 Single- and Double-beam Emission Spectra and Background Effects

Rearranging Equation (26) one obtains \(L_s(\tilde{\nu}, T_s)\), the single-beam emission spectrum of the sample (Equation 33):

\[
L_s(\tilde{\nu}, T_s) = \varepsilon_s(\tilde{\nu}) \times L_{\text{bb}}(\tilde{\nu}, T_s)
\]  

This relation shows that the so-called single-beam emission spectrum of any sample at a certain temperature can be viewed as its emittance, \(\varepsilon_s(\tilde{\nu})\), modulated by the blackbody radiation spectrum corresponding to the same temperature.

In the ideal case, if the detector received radiation only from the sample and responded to it perfectly, \(L_{\text{bb}}(\tilde{\nu}, T_s)\) could be replaced by the corresponding Planck function, \(H(\tilde{\nu}, T_s)\), yielding Equation (34):

\[
L_s(\tilde{\nu}, T_s) = \varepsilon_s(\tilde{\nu}) \times H(\tilde{\nu}, T_s)
\]  

However, the actually measured spectra are affected by background radiation, \(B(\tilde{\nu})\), and by imperfections of the instrument used. To account for these effects one can write Equation (35):\(^8\)

\[
L_s(\tilde{\nu}, T_s) = R(\tilde{\nu}) \times [\varepsilon_s(\tilde{\nu}) \times H(\tilde{\nu}, T_s) + B(\tilde{\nu})]
\]  

where \(R(\tilde{\nu})\) is the instrument response function (in the ideal case \(R(\tilde{\nu}) = 1\)). \(B(\tilde{\nu})\) represents background radiation of different origin often written as the sum of two terms, \(B(\tilde{\nu}) + I(\tilde{\nu}) \times \rho(\tilde{\nu})\), to distinguish between self-radiation of the instrument, and outside radiation reflected off the sample. Equation (35) assumes a detector kept at or near 0 K, which is rarely the case. With liquid-nitrogen-cooled detectors \((T_d = 77 \, \text{K})\) Equation (35) is a good approximation. However, if a room-temperature detector is used which emits a fair amount of energy, the above equation must be extended to Equation (36), with one more term corresponding to its radiation:\(^10\)

\[
L_s(\tilde{\nu}, T_s, T_d) = R(\tilde{\nu}) \times [\varepsilon_s(\tilde{\nu}) \times H(\tilde{\nu}, T_s)
- \varepsilon_d(\tilde{\nu}) \times H(\tilde{\nu}, T_d) + B(\tilde{\nu})]
\]  

**Figure 6** Comparison of emission and absorption spectra of a poly(methyl methacrylate) (PMMA) film: (a) Single-beam emission spectrum of PMMA film on an Al foil at 120 °C; (b) blackbody reference emission spectrum at 120 °C; (c) double-beam emittance spectrum of PMMA obtained as a ratio of A to B; (d) transmittance spectrum of the same PMMA film measured in reflection–absorption mode (* indicates chloroform inclusion bands).
where $\varepsilon_d$ is the emittance of the detector and $T_d$ is its temperature (note the negative sign of the added term, meaning opposite direction of that radiation flux).

A similar relation can be written (Equation 37) for the measured single-beam emission spectrum of the laboratory blackbody reference:

$$L_{bb}(\tilde{\nu}, T, T_d) = R(\tilde{\nu}) \times [H(\tilde{\nu}, T) - H(\tilde{\nu}, T_d) + B(\tilde{\nu})]$$

(37)

where it has been assumed that $\varepsilon_{bb}(\tilde{\nu}) = \varepsilon_d(\tilde{\nu}) = 1$.

Now the emittance of the sample, $\varepsilon_s(\tilde{\nu})$, cannot be obtained as the ratio of $L_s$ and $L_{bb}$, as has been defined in Equation (26), unless the last two terms in Equation (36) are eliminated. The standard procedure to do it involves making four measurements: the emission spectra of both the sample and the blackbody reference are measured at two temperatures; then, assuming that the sample emittance is independent of temperature over the operating range, the emittance of the sample can be calculated as the ratio of the increase in sample luminance to that of the blackbody luminance (Equation 38):

$$\varepsilon_s(\tilde{\nu}) = \frac{L_s(\tilde{\nu}, T_2) - L_s(\tilde{\nu}, T_1)}{L_{bb}(\tilde{\nu}, T_2) - L_{bb}(\tilde{\nu}, T_1)}$$

(38)

where $T_2 > T_1$. Substituting the full expression for luminances from Equations (36) and (37) into Equation (38) it can be seen that using this procedure, which is referred to as background correction, all terms that do not depend on sample temperature are, in principle, eliminated.

When a low-temperature detector is used, $B(\tilde{\nu})$ includes radiation emitted by the surface of the beamsplitter in the interferometer (oxide species formed on the surface of the semi-transparent Ge layer) mainly responsible for the so-called instrument self-emission. It has been found (11) that subtraction of the interferograms rather than the single-beam spectra in Equation (38) leads to better compensation of the beamsplitter emission, since this avoids some phase-correction problems. Radiation originating in the beamsplitter suffers a different number of reflections in the interferometer than radiation coming from the sample, which creates different phase relations for this part of the signal, not correctly accounted for in the process of phase correction that follows Fourier transformation. (12) Figure 7 shows a typical example of background correction in the case of a cooled MCT detector. (8) One can see that the spectral features can be identified in the uncorrected spectrum (broken line) as well, but the relative intensities are strongly altered. Hence, in quantitative analysis based on emission spectra background correction is obligatory.

### 2.4.2 Role of Instrument Response

Equations (35–37) show that the instrument response function, $R(\tilde{\nu})$, has an impact on the appearance of single-beam emission spectra. Consequently, $R(\tilde{\nu})$ can be determined experimentally by comparing the emission spectrum of a good laboratory blackbody to

![Figure 7 Emittance spectra of PMMA film using an mercury cadmium telluride (MCT) detector: (a) with background correction, and (b) without background correction. (Reproduced by permission of the Society of Applied Spectroscopy from Chase, Appl. Spectrosc., 35, 77–81 (1981).) (8)](image-url)
the appropriate Planck functions. For instance, using a room-temperature detector, stray radiation of the room-temperature surroundings (background) can be neglected, and $R(\tilde{v})$ can be obtained from Equation (37) as follows, from Equation (39):

$$R(\tilde{v}) = \frac{L_{bb}(\tilde{v}, T_i, T_d)}{[H(\tilde{v}, T_i) - H(\tilde{v}, T_d)]}$$

(39)

i.e. as the ratio of the measured single-beam blackbody spectrum to the difference of two theoretical blackbody emission curves corresponding to the temperature of the sample and the detector, respectively. $R(\tilde{v})$ is expected to be independent of sample temperature but the precision of its determination is the higher, the greater the temperature difference.

The explicit knowledge of $R(\tilde{v})$ is not necessary when working with double-beam emittance spectra, but it may prove very useful in several other applications:

- Blackbody reference spectra can be simulated for any desired temperature by multiplying $R(\tilde{v})$ with the corresponding Planck function, which can save time by eliminating a great number of reference measurements;
- Single-beam emission spectra can be corrected for instrumental distortions if they are divided by $R(\tilde{v})$;
- If the temperature of a blackbody radiator is to be determined, before fitting the Planck functions to the measured single-beam spectra they must be corrected for detector temperature and instrument response.$^{(9)}$

2.4.3 Effect of Sample Temperature

In order to be detected, the radiating sample may be warmer or cooler than the detector (Figure 8), i.e. in the absence of a temperature difference there is no signal (no interferogram in case of an FTIR measurement). The signal appears when $\Delta T = T_s - T_d > 0$ and it grows with increasing $\Delta T$. (The sign of the temperature difference is not reflected in the single-beam spectrum, but the interferogram gets inverted when $\Delta T$ is negative.)

The temperature dependence of single-beam spectra originates from the temperature dependence of the Planck function (see Equation 18 and Figure 3), which is reflected also in the Stefan–Boltzmann law (Equation 10). It is anticipated that owing to this very strong temperature dependence of the intensity of single-beam emission spectra, the sample temperature must be strictly controlled and held constant during data acquisition.

Band intensities in double-beam emission spectra do not show temperature dependence (see Figure 8), unless chemical or structural modifications take place.$^{(8)}$ This follows from theory: when ratioing the single-beam emission spectrum of the sample to that of the blackbody (measured at the sample temperature), the factors depending on temperature will be eliminated. Nonetheless, any temperature mismatch between sample and reference (blackbody) will show up in the spectrum

Figure 8 Emittance spectra of a polystyrene film: (a) at 40°C and (b) at 10°C (with the detector at 25°C). (Reproduced by permission of the Society of Applied Spectroscopy from Chase, Appl. Spectrosc., 35, 77–81 (1981).$^{(8)}$)
The thickness of condensed-phase samples is a critical parameter in IRES when conventional methods of thermal excitation are used (samples in thermal equilibrium and no temperature gradient across the sample). Theory and practice have shown that the ideal sample thickness for IR emission spectroscopy is the same as for IR absorption spectroscopy, i.e. 1–5 µm. With the increase of sample thickness, the intensities of emission bands will increase and broaden gradually, so that spectral contrast gets worse and worse (see the lower three traces in Figure 10). Excessive thickness makes the sample opaque (nontransparent) when the single-beam emission spectrum of a semitransparent material becomes continuous like that of the blackbody. In this case the emission spectrum is no longer characteristic of the material and depends mainly on the temperature of the sample.

The quantitative relationship (Equation 40) between thickness and sample emittance is given by the emission spectroscopic equivalent of the Lambert–Beer law (valid if Equation 32 holds):

\[
\varepsilon(\tilde{v}) = 1 - \tau(\tilde{v}) = 1 - 10^{-K(\tilde{v})d}
\]

where \( K(\tilde{v}) \) is the linear decadic absorption coefficient of the material and \( d \) is the layer thickness; for solutions or gas mixtures \( K(\tilde{v}) \) is replaced by \( b(\tilde{v}) \times c \), where \( b \) stands
for the molar decadic absorption coefficient (usually also denoted by \( \varepsilon \)), and \( c \) is concentration. The connection to the absorbance of the sample, \( A(\tilde{\nu}) \), which is the linear intensity scale used in absorption spectrometry, is given by Equation (41):

\[
A(\tilde{\nu}) = K(\tilde{\nu}) \times d = - \log[1 - \varepsilon(\tilde{\nu})]
\]  

(41)

2.4.5 Problems Expected with Condensed-phase Samples

An emission experiment, in fact, differs from the simple transmission–reflection model depicted in Figure 5(a) in that the emitted radiation originates within the sample and goes in every direction in space, but we observe only radiation emerging from a given direction within a certain solid angle, as shown in Figure 5(b). Several papers have dealt with theoretical models and suggested approximate expressions for the emittance of semitransparent condensed-phase samples under various sampling conditions.\(^{13-17}\) Single and multiple layers of samples have been considered in different arrangements, e.g. between IR transmitting windows, between a reflecting metal back-plate and a window, or on a back-plate but without a window, etc. These treatments are based on ray tracing and energy conservation at all interfaces while considering the optical properties of the materials: internal transmittance and possible reflections at the interfaces.

Perhaps the most comprehensive treatment can be found in the publications by Hvistendahl et al.\(^{15}\) and Ryttner\(^ {16}\) who have also pointed out some errors in earlier publications. For a simple case that is often used in practice, an uncovered layer of liquid or solid sample on a perfectly reflecting back-plate support, the emittance can be expressed (Equation 42) through the internal transmittance of the sample (\( \tau \)), and its reflectance at the front surface (\( \rho \)) as

\[
\varepsilon = \frac{1 - \rho(1 - \tau^2)}{1 - \rho \tau^2}
\]  

(42)

which refers to double pass of the emitted radiation through the layer (compare with the basic Equation 30). For detailed results concerning multilayered samples or other methods of observation, the original papers should be consulted.\(^ {15,16}\)

2.4.6 Reduced Emission Phenomena: Surface Reflectivity and Self-absorption

In case of measurements of solids and liquids, irregular or distorted band shapes are often observed, especially for strong bands near their peaks. This is usually referred to as reduced emission phenomena.\(^ {17}\) In addition to reduced relative band intensities as compared to those observed in the absorption (transmittance) spectrum, some part of the band peak seems to be missing, leading to inversion of the peak and apparent splitting of the band. This can be seen on the spectra of the thick samples in Figure 10.\(^ {18}\) Two explanations have been put forward to explain this phenomenon: surface reflectivity and self-absorption.

It has been shown,\(^ {15,16}\) that surface reflectivity appearing in the expressions of sample emittance (e.g. in Equation 30) may be responsible for such distortions because of variations (sudden increase and decrease) of reflectivity in the vicinity of strong absorption bands, which cannot be neglected. These authors have used the damped harmonic oscillator model to simulate this phenomenon (see Figure 11a and b), and have shown that surface reflectivity leads to asymmetric distortion of strong emission bands.

A simple and effective practical method has been proposed to eliminate this kind of distortion: to use, instead of a laboratory blackbody as reference, a sufficiently thick, opaque sample (for which \( \tau = 0 \)) of the same material as the sample. The quantity obtained this way (Equation 43):

\[
\varepsilon^* = \frac{L_s}{L_{op}} = \frac{\varepsilon_s}{\varepsilon_{op}}
\]  

(43)

is referred to as emittance with an opaque sample as reference. Since the thin and thick samples have approximately the same surface reflectivity, this procedure diminishes its influence and distortion-free emittance spectra can be obtained. (See an example in Figure 11c and d.)

Griffiths\(^ {12}\) attributed some reduced emission phenomena to self-absorption, i.e. to reabsorption of radiation originating in the bulk of the sample by the colder surface layer. This can also be verified theoretically using similar spectral simulations\(^ {10,16}\) as above leading to Equations (44) and (45):

\[
\varepsilon(\tilde{\nu}) = (1 - \tau_b)\tau_s
\]  

(44)

or

\[
\varepsilon(\tilde{\nu}) = (1 - \tau_s^2)\tau_s
\]  

(45)

corresponding to emitting samples without or with a reflecting back-plate, respectively, where \( \tau_b \) and \( \tau_s \) are transmittances of the bulk and surface layer, respectively, depending on the respective thicknesses (\( d \)) as Equation (46):

\[
\tau(\tilde{\nu}) = 10^{-K(\tilde{\nu})d}
\]  

(46)

Calculations show (see Figure 12) that self-absorption can lead to band splitting for strong absorptions of thin layers and also for weaker absorptions of thick
layers, and this effect leads to symmetric splitting of strong absorption bands, which allows it to be distinguished from surface reflectivity. Heating the sample from the front is expected to diminish self-absorption.

2.4.7 Sample Orientation and Metal Surface Effects

In the preceding discussion the emitted radiation has been assumed to be homogeneous and unpolarized under any viewing angle, which is correct for gas
phase work and for most condensed-phase samples. However, if the sample shows macroscopic order such that the molecules are oriented or aligned about a distinguished direction (which occurs, for instance, in oriented crystalline layers or stretched polymer films), the transition dipole moments associated with vibrational transitions also assume preferred directions in space. In this case the radiation is strongest in the plane perpendicular to the transition dipole, and is polarized in the plane defined by the propagation direction and the transition dipole.

Another practically important case is when the emitting molecules are located near a metal surface. When the distance between the surface and the molecules is very small compared to the wavelength of the emitted radiation (e.g. as in the case of adsorbed molecules), special selection rules apply, known as metal surface selection rules. Greenler has calculated the angular intensity distribution of light emitted by radiating dipoles that are parallel and perpendicular to the metal surface. His results indicate that

1. one should not expect to see IR emission from molecular vibrations whose transition moments are parallel to the surface;
2. for vibrations with transition moments perpendicular to the metal surface, the best viewing angle is 70° to 80° from the surface normal and the radiation is polarized parallel to the plane of incidence, while in the direction perpendicular to the metal surface the emission intensity is zero (see Figure 13).

These selection rules help in determining the orientation of molecules on the surface and have to be taken into account when setting up such an experiment. For instance, part of the unpolarized background radiation can be eliminated and the S/N can be substantially increased by inserting an IR polarizer into the beam or by using a polarization-modulation technique.

### 3 INSTRUMENTATION: SPECTROMETERS AND DETECTORS

Laboratory measurements in IRES can be performed with commercial IR spectrometers designed for absorption measurements to be done in the transmission regime. Some of these instruments have a provision to switch over to emission mode, or at least have an emission port on the instrument housing that can accept an auxiliary emission accessory.

---

**Figure 13** Calculated angular intensity distribution of emission by a dipole oriented perpendicularly to the metal surface (the emission angle is measured from the normal to the surface). (Reprinted from Greenler, 'Light Emitted from Molecules Adsorbed on a Metal Surface', Surface Science, 69, 647–652 © (1977) with permission from Elsevier Science.)
Commercial IR spectrometers can be divided into two broad classes: dispersive (prism or grating) instruments and FT (or interferometric) instruments. Dispersive instruments dominated IR spectroscopy from the early days of its history until the end of the 1970s, when FTIR instruments started proliferating at a great pace, together with fast digital data handling facilities.

Both dispersive and FTIR instruments are mechanical-optical devices that have the following main components:

- incandescent IR radiation source (switched off or replaced by the sample in IRES);
- a dispersion element (in the dispersive instruments) or an interferometer (in the FTIR instruments);
- an IR detector (with amplifier electronics);
- a device for recording (plotting or storing) the measured data.

The first three components are connected by optical elements (mostly mirrors) that direct, collimate or focus the light as appropriate. The radiation source and the detector are in the two terminal focal points of the spectrometer optics. The peculiarity of emission measurements is that the sample itself serves as the source of radiation; thus the sample replaces the usual light source or it is put at an optically equivalent location inside or outside the spectrometer cover (by an auxiliary port), and the conventional sample compartment remains empty.

### 3.1 Dispersive Instruments

Conceptually, the dispersive instruments are much simpler, since they measure the spectrum directly. The IR beam to be analyzed is dispersed by a prism or more commonly by a diffraction grating to spatially separate the different wavenumber components, and the optical image of the spectrum is scanned through with a narrow slit permitting only energy from a narrow spectral interval to fall on the detector. During the scan, the intensity of the radiation is recorded as a function of wavenumber.

To suit the requirements of the much more commonly used transmission spectrometry, most dispersive IR spectrometers are built as double-beam instruments with optical-null or ratio-recording detection (shown schematically in Figure 14). Their working principle is as follows: the radiation emitted by the IR source is divided by symmetrically arranged mirrors into two equivalent beams, the sample beam and the reference beam, both passing through the sample compartment next to each other. The beams are focused on the entrance slits of the monochromator and are combined by means of a rotating chopper into one common path, letting the alternating sample and reference beams fall on the dispersing element, then through the exit slit of the monochromator on the detector. The spectrum is recorded in real time (during scanning) as the ratio of the sample beam intensity \( I \) to the reference beam intensity \( I_0 \).

In a transmission measurement the emitter is an incandescent light source operating at above 1000 K (such as a Globar or a nichrome filament); from its radiation the sample is supposed to absorb more energy than the reference, thus the recorded intensity ratio gives the transmittance of the sample relative to that of the reference: \( t(\nu) = I(\nu)/I_0(\nu) \).

In contrast, in an emission measurement the standard light source of the instrument is switched off or removed and the emitting sample and a reference emitter (a laboratory blackbody) are put in its place or at optically equivalent positions. Usually some modification of the source optics is needed to accommodate both emitters in the focus of the respective paths on a joint, heated (temperature controlled) sample stage. In principle, both emitters can be put in the sample compartment as well, but then special light-gathering optics are needed to increase the throughput of the emitted radiation to the detector. Various double-beam or semi-double-beam emission source arrangements have been discussed in Huong’s review. The recorded intensity ratio, in this case, directly gives the emittance of the sample, \( \varepsilon_\nu(\nu) \), i.e. its emission intensity relative to that of the blackbody at the same temperature in accordance with Equation (26).

Although the emittance spectrum can be directly measured with a double-beam grating spectrometer, these instruments are rarely used today in emission spectroscopy, partly because of the overwhelming technical advantages of FTIR instruments for detection of weak signals, and also because two costly emission attachments are needed.

### 3.2 Fourier Transform Infrared Instruments

FTIR spectrometers measure single-beam spectra (or rather interferograms corresponding to single-beam spectra) directly, thus the method by which emittance spectra are obtained is quite different from the way they are measured on a double-beam grating spectrometer. The usual procedure of measuring \( \varepsilon_\nu(\nu) \) on an FTIR spectrometer is to measure the reference (e.g. blackbody) interferogram first, store the

---

**Figure 14** Optical scheme of a double-beam dispersive IR spectrometer. (PM, paraboloid mirror; EM, ellipsoid mirror.)
measured data in the memory of the computer and calculate the single-beam reference spectrum; the sample is then inserted in the emission accessory and the same operations are done with the sample to obtain its single-beam spectrum. Finally, the desired double-beam spectrum (the emittance spectrum) is calculated as a point-by-point ratio of the two single-beam spectra.

The schematic optical layout of an FTIR spectrometer equipped with an auxiliary emission accessory is shown in Figure 15. The heart of an FTIR spectrometer is the Michelson interferometer consisting of a beamsplitter and two mutually perpendicular mirrors, one fixed and the other moving back and forth at a constant velocity. The collimated IR radiation enters the interferometer and falls on the beamsplitter (a semitransparent, semireflecting material) at 45° where it is divided into two equal parts and travels towards the two mirrors. The reflected beams returning from the fixed and moving mirrors with changing path difference are combined together at the beamsplitter where they interfere with one another. This interference causes variations in the instantaneous intensity of the beam that is focused on the detector. The measured intensity, \( I(\delta) \), of the modulated beam as a function of optical path difference, \( \delta \), in the two arms of the interferometer is called the interferogram; it contains multiplex information from all spectral elements in each data point. The interferogram, \( I(\delta) \), and the single-beam spectrum, \( L(\tilde{\nu}) \), are FT pairs, thus the spectrum is obtained from the digitized interferogram by Fourier transformation (Equation 47):

\[
L(\tilde{\nu}) = \int_{-\infty}^{\infty} I(\delta) \cos 2\pi \tilde{\nu} \delta \, d\delta
\]  

For a most comprehensive description of the theory and a wide range of practical aspects of FTIR spectrometry the reader is referred to the monograph written by Griffiths and deHaseth.\(^{12}\)

With an FTIR instrument, other optical arrangements are also possible, e.g. the radiating sample could replace the detector when an auxiliary detector is used, but this is rarely a practical solution. For versatility it is essential that the instrument be equipped with an emission port easily accessible through a flip mirror to accept light from an auxiliary emission attachment.

3.1.1 Advantages of the Fourier Transform Infrared Technique

For all the complexity of its operation principle, the interferometric measurement technique offers several advantages compared with conventional dispersion IR spectroscopy.

**Higher Signal-to-noise Ratio** Under conditions of equal measurement time, FTIR spectra show higher S/N. This is the consequence of two factors:

1. the higher optical throughput of the interferometer than that of a grating monochromator (a factor of 50 to 200, due to elimination of the narrow optical slits);
2. the so-called multiplex advantage arising from the fact that in FTIR all of the spectral elements are observed for the whole measurement time, while in a grating instrument the measurement time has to be divided by the number of resolution elements in the whole spectrum. For the whole IR region at a resolution of 4 to 1 cm\(^{-1}\) this gives a gain factor of 30 to 60 in S/N, and even more at higher resolutions. Higher S/N means higher sensitivity, which is essential in IRES measurements, especially when the temperature difference between sample and detector is relatively small and low radiation levels have to be measured.

**Greater Frequency Accuracy** The interferometers of FTIR instruments have a built-in visible laser reference to control the mirror movement, which helps determine the wavenumber scale of the spectrum with very high accuracy (no additional wavenumber calibration is needed except for high-resolution spectra).

**Computerized Data Handling** Computerized data handling is not limited to FTIR systems but because of the need to store the measured data in digital form and to perform the Fourier transformation and other necessary calculations before the spectrum is obtained, FTIR spectrometers are ab ovo equipped with dedicated microcomputers or are connected to PCs and work under computer control. The instrument manufacturers supply
proprietary software with the instrument for data acquisition and analysis, which may incorporate interactive tutorials and integrated diagnostics packages as well.

Based on the above advantages, FTIR spectrometers as of today are preferred to dispersive machines in most IRES applications. There are more than half a dozen well-known instrument manufacturers in the market offering good-performance FTIR instruments in a broad price range (from $30,000 to $150,000) that are meant basically for transmission work. The cheaper models may be adequate for routine laboratory measurements to obtain qualitative data at low spectral resolution (max. 1 cm\(^{-1}\)), and are usually limited to the 4000 to 400 cm\(^{-1}\) spectral range. The more expensive ones are supposed to have a higher-quality interferometer (featuring dynamic alignment, possible step-scan operation) suitable for higher-resolution work (at least 0.1 cm\(^{-1}\)), and be more versatile, offering a choice of built-in interchangeable components, e.g. different detectors, beamsplitters and sources to cover the entire spectrum from the FIR to the NIR. While faster scanning instruments with high optical throughput are always preferred for IRES, high resolution is needed only for gas-phase work, for sure identification of unexpected species with resolvable rotational fine structure. Lower-resolution spectra with higher S/N are more useful in most quantitative applications than highly resolved but noisy spectra.

3.3 Open-path Fourier Transform Infrared Instruments

One of the natural applications of IRES, remote sensing, stems from its single-ended measurement geometry allowing the observation of spectra of thermal emitters located at a distance from the instrument. Since atmospheric or environmental studies of emission sources most often involve field measurements, the instruments used must be mobile, i.e. mounted on a vehicle, or be compact and lightweight to be carried more easily. For this purpose dedicated open-path Fourier transform infrared (OP/FTIR) spectrometers are used that are equipped with a telescope to collect the radiation and matched transfer optics to pass a collimated beam into the interferometer.

One of the most popular designs consists of a 25-cm Newtonian telescope and a standard Michelson interferometer with a liquid-nitrogen-cooled MCT detector. A simplified optical diagram of such an instrument is shown in Figure 16. The spectrometer is mounted on the top of the telescope barrel making a very compact structure that can be set up on a tripod stand to point it conveniently toward the remote source. The instrument can run on battery power and may be controlled by a portable laptop computer in remote locations. Other OP/FTIR spectrometers may incorporate a Cassegrain-type telescope, a more sensitive liquid-helium-cooled detector (especially for the FIR region, in high altitude and extraterrestrial measurements), and provision for measurement of blackbody reference spectra or calibration standards for quantitative analysis. With the addition of a portable artificial IR source (equipped with a source telescope) or a remote cube-corner array retro-reflector, these instruments can also work in transmission mode. A famous early mobile remote sensing FTIR instrument built for the United States Environmental Protection Agency (USEPA) in the 1970s around a commercial, moderately high resolution FTIR system configured to fit into a van, the so-called Remote Optical Sensing of Emissions (ROSE) system, has been described together with some of the measurement results.

Obtaining the appropriate blackbody reference spectrum may pose some problem, since in the case of remote natural sources of radiation the temperature of the source may not a priori be known. Knowledge of the instrument response in this case may prove useful, since it allows easy simulation of single-beam blackbody reference spectra from Planck functions for various temperatures (see section 2.4). After dividing the sample spectrum by the trial reference spectra, the one giving a double-beam (emittance) spectrum with the flattest background will correspond to the right temperature.

A serious limiting factor of the applicability of IRES in environmental or remote atmospheric measurements (e.g. the measurement of the plume of a power plant smokestack or hot gases from combustion jets) is atmospheric absorption. Since there is a great absorbing pathlength (typically from several meters to about a kilometer) between the remote source and the spectrometer, atmospheric water vapor and CO\(_2\) may completely block certain spectral regions, prohibiting the detection of some pollutants.
3.4 Choice of Detectors

The description of IR detectors is beyond the scope of this article, but one should be aware of how an emission measurement is affected by the type of detector used, and choose the detector or treat the data accordingly.

There are two basic types of IR detectors: room temperature pyroelectric detectors and cooled quantum detectors. To a first approximation a detector can be characterized by its operating range and its specific detectivity, $D^* \times \lambda$, which depends on wavenumber. Broad-range detectors that can be used in the whole IR region are less sensitive than narrow-range detectors. The most commonly used room-temperature detectors are triglycine sulfate (TGS) and DTGS, the latter being several times more sensitive in the whole IR region. The most popular cooled, broad-range detector is the photovoltaic MCT detector (MCT, HgCdTe) operating at liquid-nitrogen temperature (77 K). The MCT detector is by more than an order of magnitude more sensitive than DTGS and its response to the changing signal is also incomparably faster, allowing the measurement rate to be increased to 5–10 interferogram scans per second (depending on resolution). Higher sensitivity detectors are available for narrower spectral regions (some may require cooling below 20 K with liquid helium); for example the InSb detector has nearly unit quantum efficiency but it does not work below 1800 cm$^{-1}$.

Based on the above properties, the cooled MCT detector could be preferred in IRES to compensate for the usually low signal level. In addition, heat radiation leaving the detector at 77 K is negligible, which means that in this way practically the full sample emission is detected (see Equations 35 and 36 and the discussion in section 2.4), even if it is not heated. One should not forget, however, that an MCT or other low-temperature detector will detect, in addition to sample emission, thermal radiation of all room-temperature objects in its field of view, including parts of the instrument itself, (e.g. the beamsplitter). Thus, with the choice of an MCT detector comes the obligation of making a correction for background radiation with the extra measurements involved, according to Equation (38).

In contrast, with the use of a DTGS detector, the sample must be kept at a temperature higher (or lower) than room temperature to get appreciable radiation flux. But although the single-beam spectrum may not be as intense (the S/N may not be as high) as with an MCT detector, the spectra obtained are usually free from spurious bands. For this reason, a room-temperature DTGS detector may be a better choice for routine IRES applications.

3.5 Custom-built Instruments for Special Applications

While commercial instruments with matched sample optics are suitable for most IRES experiments, important research fields such as the study of adsorbed species on metal single crystal surfaces or IR chemiluminescence have more stringent requirements owing to the extremely low emitted signal levels. Because of the latter, liquid-helium-cooled detectors have to be used when the sample is kept at room temperature, but then precautions must be taken to minimize background radiation.

Durana et al. have solved this problem by utilizing a cryogenically cooled FTIR spectrometer, by immersing a Michelson interferometer designed to operate at 77 K into a cold helium-purged chamber and cooling the whole optical collection system to 77 K. The equipment shown schematically in Figure 17 was equipped with a liquid-helium-cooled photoconductive Ge/Cu detector and with a gold/KRS-5 wire grid polarizer inserted into the collection beam. The samples (e.g. molecular monolayers adsorbed on metal single crystal surfaces) were maintained at a temperature between 80 and 500 ± 1 K and tilted to give an angle of incidence of 50–55° to approach the optimum
Figure 18 Schematic of a cryogenically cooled grating spectrometer used for studying adsorption on single crystal surfaces. (Reprinted with permission from S. Chiang, R.G. Tobin, P.L. Richards, J. Vac. Sci. Technol. A, 2(2), 1069–1074 © 1984 American Vacuum Society.)

Experimental conditions predicted by Greenler (see section 2.4). A similar type of cryogenic interferometer system has been used previously to carry out high-sensitivity gas-phase studies of IR chemiluminescence. The working ranges of these instruments were 2000–1250 and 2000–720 cm\(^{-1}\).

Another cryogenic spectrometer based on Czerny–Turner-type grating spectrometer (see Figure 18) was described by Richards et al. and used successfully in a series of studies of weak low-frequency adsorbate–substrate vibrations on clean, metal single crystal samples. In this case the whole spectrometer was cooled with liquid helium to 4.2 K, and was connected to an ultrahigh vacuum system sharing the sample compartment with other surface analysis methods. One advantage of this instrument over the cooled FTIR systems introduced above is the broader useful spectral range extending down to 330 cm\(^{-1}\). The authors claim that the S/N attainable with this instrument in this particular application is comparable to that of an FTIR instrument, and the grating instrument is easier to cool. Anyhow, one tends to share the opinion that this instrumental modification is really not viable for routine analytical applications.

4 LABORATORY METHODS

4.1 Conventional Methods of Thermal Excitation

As it has been mentioned above, IR detectors respond to any deviation from radiation balance between sample and detector. This means that the sample (or more precisely, the portion of sample in the field of view of the detector) must be either at a higher or at a lower temperature than the detector.

In conventional thermal emission spectroscopy the samples are heated to above room temperature and are kept at constant temperature (in thermal equilibrium) during the measurement. Various types of high-temperature or variable-temperature cells have been designed for IR transmission work, and in principle all these can also be used in IRES. Genuine emission cells, however, have a metal body (made of highly reflecting, low-emissivity material) and are backed with a reflector plate which, in addition to blocking the outside radiation, brings a twofold gain in emission intensity. The shiny metal backplate (polished stainless steel or gold-covered copper block) often serves also as a heater for liquid and solid films. Temperature feedback to the controller is provided by a thermocouple mounted in a hole drilled in the heater block.

4.1.1 Methods for Gases

The measurement of IR emission spectra of hot gases poses little problem experimentally. The temperature in this case may be high enough to produce intense spectral features, and the bands show rotational structure consisting of series of very narrow lines that are easy to identify using high resolution (at least 0.1 cm\(^{-1}\)). Also, there are no surface effects that could distort the spectral features. The pathlength requirements of the gas samples are not so stringent either as with condensed-phase
samples: pathlengths of a few millimeters to hundreds of meters or even kilometers (in case of open-path instruments) may be acceptable depending on the partial pressure of the gas.

Laboratory measurements of emission spectra of gases often serve for calibration purposes, as reference for remote sensing by IRES. These calibration spectra must be measured at known (controlled) pressure, temperature and pathlength, but may be obtained either in emission or in transmission mode, then converted to absorbance scale. For IRES measurements, the standard single-pass or multipass transmission gas cells\(^{(26)}\) surrounded with a cylindrical oven can be used (e.g. a 10-cm cylindrical Pyrex cell with KBr windows), although in this case higher background emission is expected than with a metal tube surface. Limiting the field of view with cold (water-cooled) apertures may help improve the S/N.

The potential of FTIR emission spectroscopy for the study of gas-phase molecules has been reviewed recently by Bernath.\(^{(27)}\)

### 4.1.2 Methods for Liquids

Again, conventional heated liquid transmission cells can be easily converted to emission cells by replacing one of the two parallel windows by the heatable reflecting back plate. As a horizontal liquid sample holder, flat-bottomed shallow metal cups can also be used, in good thermal contact with a heater stage (Figure 19). In horizontal liquid sample holders the top window may be omitted, although a windowed cell has some advantages;\(^{(16)}\) the sample may be compressed to a thin film between the window and the support, evaporation is minimized and a uniform sample temperature is assured with a window of high thermal conductivity, which may also minimize cooling of the surface and occurrence of self-absorption.

### 4.1.3 Methods for Solids

The most widely proliferated method is to put the sample in direct contact with an electrically heated metal block when the sample is heated from the reverse side (not facing the spectrometer). A circular, heatable metal stage of about 10–15 mm diameter may serve as a good solid sample holder, e.g. in an emission accessory shown in Figure 19. This configuration has the disadvantage that the front surface of the sample may be somewhat cooler than the bulk and reabsorption of the emitted radiation may occur, leading to distortions and splitting of emission bands as described earlier.

Horizontal sample stages are more practical in case of some solid samples, as well: they hold polycrystalline or powdered samples more easily than vertical or tilted sample holders. Good adhesion to the support for better heat transfer may be facilitated by depositing the sample on the support from solution or suspension by slow evaporation of the solvent. The optimum amount of sample to deposit is around 0.1 mg cm\(^{-2}\). Unless the sample is too thick, a useful emission spectrum can be obtained from uneven layers or chunky materials as well, but the spectral contrast may deteriorate considerably compared to the spectra of even and smooth emitting layers. For polymer films or other smooth layers of neat materials the ideal sample thickness is in the range of 1–5 µm.

Microreactor-type sample cells have also been built, for example for in situ studies of heterogeneous catalytic reactions.\(^{(28)}\) They are based on quartz, Pyrex glass or stainless steel chambers that withstand high temperatures, can be evacuated or placed under pressure, and purged with gases as necessary and are equipped with the usual heating and temperature controlling facilities. A typical catalytic microreactor design is shown in Figure 20.

### 4.1.4 Samples at Ambient or Low Temperatures

There are several ways to avoid cooling of the front surface. Naturally, it should not occur with the use of a
cooled detector if the sample is kept at ambient temperature, or with the use of a room-temperature detector if the sample is cooled. Under these circumstances, however, the measurement is practically restricted to the spectral region below 2000 cm\(^{-1}\) because the maximum of available energy will be that of a 300 K blackbody (see Figure 3), and the signal, if any, would hardly exceed noise level at higher frequencies.

4.1.5 Laboratory Blackbody Sources

There is a great variety of so-called laboratory blackbody emission sources used to provide a reference or calibration standard for thermal emission measurements. A heated black-walled cavity with an aperture makes a good approximation to an ideal thermal emitter (with emittance close to 0.99), and commercial blackbody calibration sources are of this type. These devices have precise temperature control (some of them up to 3000 K) but since they are usually too large to fit into most emission accessories designed for microsamples, they are used mostly in gas-phase work and remote sensing.

With condensed-phase samples, it is desirable also that exactly the same optical arrangement be used with the same heater and temperature controller settings in both sample and reference measurements. Thus, perhaps the most convenient choice in practice is to use a metal plate covered with a thick layer of heat-resistant matt-black paint; but there are some other suitable black materials such as a sooted metal disc or aluminum foil, a graphite disc or a layer of carbon black on the standard sample stage. One should keep in mind, however, that the emittance of these laboratory blackbodies may not exceed 0.9.

4.1.6 Emission Accessories

An emission accessory consists of a controlled-temperature sample cell placed in the focus of a light collection optics (normally an off-axis ellipsoid or off-axis paraboloid mirror) that sends the radiation into the spectrometer. Ideally, the cell is mounted on a three-dimensional (3-D) translation stage to facilitate sample alignment. Solid sample holders may require a tilting stage. One should keep in mind also that exactly the same optical arrangement be used with the same heater and temperature controller settings in both sample and reference measurements. Thus, perhaps the most convenient choice in practice is to use a metal plate covered with a thick layer of heat-resistant matt-black paint; but there are some other suitable black materials such as a sooted metal disc or aluminum foil, a graphite disc or a layer of carbon black on the standard sample stage. One should keep in mind, however, that the emittance of these laboratory blackbodies may not exceed 0.9.

4.2 Advanced Methods for Solids

The greatest challenge of IRES is to obtain meaningful spectra (having vibrational structure) of thick, opaque solid samples. We have seen that conventional thermal excitation by heating the sample from the rear is unable to solve this problem. However, heating of the sample can be accomplished by various means from the front, as well. In addition, by simultaneous heating and cooling of different points of the sample, temperature gradients can be maintained or generated temporarily or periodically along the thickness of the sample, which creates favorable conditions for observation of emission from a thin surface layer. Thus, irradiation of the front surface with laser beams, both visible and NIR, pulsed or continuous wave, and also blowing the surface with a stream of hot air have been tested.

4.2.1 Laser-induced Thermal Emission

One of the recent developments is laser-induced thermal emission spectroscopy (LITES). Results of the preliminary investigations in LITES have shown that it is a feasible approach because heat generation via absorption of laser light by the sample is more or less localized on its surface, regardless of the thickness, shape and composition of the sample or the support material. This means that sample thickness is no longer a limiting factor, i.e. emission spectra of the surface layers of thick samples or objects of any dimensions can be measured. However, the efficiency of this method depends on the absorptivity of the sample at the laser wavelength. Thus, for some samples (e.g. red paint) the 514.5 nm green line of an Ar-laser may be quite efficient while in general a NIR neodymium yttrium aluminum garnet (Nd/YAG) laser is thought to be a better choice.

4.2.2 Methods of Transient Heating

Excitation of thermal emission of the surface layer by a continuous-wave laser is not without difficulties because owing to thermal diffusion the thickness of the heated emitting layer increases with time, which causes a gradual deterioration of spectral contrast. This effect can be reduced by various regimes of transient or modulated heating. Fully successful LITES experiments have been described with the use of the experimental set-up shown in Figure 21 where heat build-up in the sample is prevented with a cooling gas jet directed next to the heated spot on a rotating sample. Under such conditions a transiently heated thin surface layer is generated in the sample, and it is only the emission of this surface layer that is detected. If instead of a continuous laser a pulsed laser is used in conjunction with a rotating sample, the cooling gas jet can be omitted.

A much more economical but similarly successful version of the transient-heating method uses a hot-gas jet in place of a laser to heat the surface of the sample (Figure 22). This heat source combined with a rotating
With these methods, termed TIRES, analytically useful IR emission spectra can be obtained from optically thick samples as well (see Figure 23).

4.2.3 Modulated Heating

Another new method devised for the study of high-opacity, refractory materials is named modulated emission spectroscopy (MES). It uses an argon ion laser as a pump source modulated by a wheel chopper, while the sample sits on a metallic rod immersed in liquid nitrogen. Note that modulated heating (as with pulsed lasers) requires more complex and costly electronics ensuring...
the synchronization of signal sampling with the frequency of modulation or laser firing.

The main advantage of the methods outlined above (LITES, TIRES, MES) is the ability to measure emission spectra of thick samples. It is also possible to perform depth probing by changing the heating-and-cooling regime and hence the thermal diffusion length in the sample.

Beside the indisputable advantages of TIRES, it should be mentioned that some uncertainty arises when converting the single-beam emission spectra to the double-beam emittance scale. The problem is that the heating regimes are not exactly identical between different samples or between sample and blackbody reference. The temperature of the emitting layer is not exactly known and hard to reproduce, thus the comparison of emission intensities and the quantitative evaluation of spectra obtained with the TIRES method is not so straightforward.

4.2.4 Transient Cooling and Emission–Absorption Spectra

Self-absorption is usually considered an unwanted phenomenon. There are instances, however, such as multilayer samples or formation of surface species, when weak negative spectral features appear on the background of continuous, blackbody-like emission of the bulk at characteristic frequencies of some surface species. It has been recognized that these features are not always due to surface reflection, but may be due to appearance of absorption bands on the emission continuum of the bulk.\(^{(37)}\) In such cases reabsorption of the bulk radiation by the surface species may be a chance to detect surface species on opaque substrates. If the specific application makes it desirable to exploit reabsorption, it can be fostered by cooling the front surface of the hot sample by a stream of cold air or inert gas. This method of measurement, first reported by Jones and McClelland\(^{(37)}\) and later augmented with unsteady-state heat-flow calculations and harmonic oscillator modeling,\(^{(38)}\) has been dubbed transient infrared transmission spectroscopy (TIRTS) or infrared emission with transient cooling (IRE/TC). It can be considered as the opposite of transient heating TIRES; not surprisingly, the two methods perform very similarly.

There are other instances when the emitting lower layer is not thick enough to be opaque, but a chemically different surface layer appears to absorb at its characteristic frequencies from the emission spectrum of the lower layer in regions of spectral overlap. Such spectra, containing positive and negative bands alike, are hard to interpret by conventional methods. They may be called emission–absorption spectra, and require spectral simulation and modeling to be fully understood.\(^{(10)}\)

5 COLLECTION, HANDLING AND PRESENTATION OF SPECTRAL DATA

5.1 Data Acquisition and Reduction

In view of the relatively low signal level of IR emission spectra, high-speed, high-sensitivity FTIR instruments are commonly used in IRES. With these instruments 1 to 10 interferograms can be measured in a second, so in order to increase the S/N it is feasible to accumulate and average several hundred or even several thousand scans (S/N increases as the square-root of the number of scans). Fourier transformation of the final interferogram using the fast Fourier transform (FFT) algorithm\(^{(12)}\) of Cooley and Tukey is just a matter of seconds on PCs for spectra at medium resolution (1–2 cm\(^{-1}\)). With condensed-phase samples there is usually no need to use higher than 4 cm\(^{-1}\) resolution, since the natural band widths are generally much greater, and higher resolution is concomitant with higher noise.

The advanced data-handling software accompanying most commercial FTIR spectrometers allows the smoothing of noisy spectra, the increase of the apparent spectral resolution by deconvolution techniques, the decomposition of overlapping bands, and the plotting of the spectra in any desired format, etc. These possibilities do not exist without a computer being interfaced with the instrument. Emission spectroscopy may require a few special data-processing operations that are not necessarily found in the otherwise user-friendly, menu-driven software of some commercial systems (e.g. the transformation from emittance to absorbance, and the generation of theoretical blackbody emission spectra). Thus it may prove very handy to have access to independent multipurpose spectroscopy software (such as SpectraCalc or GRAMS/32 of Galactic Industries Corporation) or to general purpose data-handling programs (such as the Microcal Origin of Microcal Software, or the Mathlab of The MathLab).

5.2 Presentation of Emission Spectra: Intensity Scales

Sometimes the single-beam spectra are presented as the final result of the measurement. Alternatively they can be converted to double-beam spectra by dividing them by a reference spectrum measured at the same temperature, with the aim of obtaining a uniform intensity scale throughout the whole spectral region of the measurement and of eliminating the instrumental distortion effects. In the IRES literature three kinds of double-beam emission spectra are encountered:\(^{(10)}\)

1. relative emittance, \(\varepsilon^\text{rel}\), obtained as \(L_x(T)/L_0(T)\), i.e. when the sample emission spectrum is divided by the emission spectrum of a reference material other
3. reflection-corrected emittance, $e^*$, obtained as $L_s(T)/L_{bb}(T)$ or according to Equation (38);

3. reflection-corrected emittance, $e^*$, obtained as $L_s(T)/L_{bb}(T)$ or according to Equation (38);

4. Quantitative Aspects

As we have seen above, Equations (40) and (41) provide the connection between emittance ($e$), transmittance ($\tau$) and the linear intensity scale, absorbance ($A$). Although Equation (40) containing the decadic (base 10) absorption coefficients is the most frequently used form of the Lambert–Beer law, for the sake of completeness we give here all versions including those written in terms of the napierian (base $e$) absorption coefficients (Equations 48 and 49):

$$
e^* (\nu) = 1 - 10^{-K(\nu)cd} = 1 - 10^{-b(\nu)cd} \quad (48)$$

$$
e^* (\nu) = 1 - \tau(\nu) = 1 - \exp[-\alpha(\nu) cd]$$

$$
= 1 - \exp[-\kappa(\nu) cd] \quad (49)
$$

where $K(\nu)$ and $b(\nu)$ are the linear and molar decadic absorption coefficients, while $\alpha(\nu)$ and $\kappa(\nu)$ are the linear and molar napierian absorption coefficients, respectively; $d$ is the sample thickness or pass length, and $c$ is the concentration. The quantities called linear are used in case of neat, condensed-phase samples, and those called molar are used in case of solutions, mixtures or gases.

In case of multicomponent samples the absorbance spectrum can be expressed through the emittance spectra of the components as follows (Equation 50):

$$
A(\nu) = -\log[1 - \varepsilon(\nu)] = \sum_i^n \varepsilon_i(\nu) c_i d \quad (50)
$$

where $n$ is the number of components.

Another method increasingly used for qualitative evaluation of single-beam emission or double-beam emittance data directly (without transforming to absorbance scale) is partial least squares (PLS) multivariate calibration.\(^{(39,40)}\) With this method in some cases even better precision can be achieved than is possible with the use of a more traditional univariate analysis, especially when one has to deal with overlapping bands belonging to different chemical species.

6 CONCLUSION AND FUTURE PERSPECTIVE

As we have seen, the fundamental principles and governing laws of IRES with thermal excitation are firmly established; the various sources of distorting effects observed in the spectra are well understood and correction methods have been developed. Compared with IRAS, the S/N in an emission experiment is from 0.2 to 2 orders of magnitude smaller; but in principle, IRES should be more sensitive than IRAS, because it measures the neat sample signal instead of the changes in a continuous, high-intensity background created by the light source used in absorption spectroscopy.\(^{(27)}\) IRES may live up to these expectations as soon as an IR avalanche detector (the IR analog of a photomultiplier tube) becomes available for the measurement of very low radiation levels.

Nevertheless, the present level of IR technology already makes IRES an attractive and very useful tool that offers solutions to problems in many branches of chemistry and technology. A recent literature survey\(^{(41)}\) shows continued interest in application of IRES to very diverse areas such as: remote sensing and open-path atmospheric monitoring, IRES studies of chemical reactions through highly vibrationally excited reaction products, in situ and real-time monitoring of chemical reactions, deposition processes, etc. the study of vibration-rotation bands of stable and transient molecules, photoluminescence and chemiluminescence. An emerging new field of application of the transient IR spectroscopic methods is the determination of chemical and physical properties of solids and viscous liquids in a moving stream.\(^{(42)}\) With further advancement this technique can lead to real-time, on-line
process control, e.g. in certain production plants or in waste processors.

Gas chromatography/infrared (GC/IR) spectroscopy coupling combines the separation power of high-resolution gas chromatography (HRGC) to the highly specific identification technique, infrared (IR) spectroscopy, based on the absorption of IR radiation by the molecules. Relying on different molecular properties, IR is an excellent complement to mass spectrometry (MS) in structural analyses. For volatile compounds, the coupling of gas chromatography/mass spectrometry (GC/MS) has been the universal basic technique for a long time. The advantages of Fourier transform infrared spectroscopy (FTIRS) allowed the coupling of gas chromatography (GC) to an FTIR (Fourier transform infrared) spectrometer, ending with a powerful tool, gas chromatography/Fourier transform infrared spectrometry (GC/FTIRS). The first device developed to interface a gas chromatograph to an FTIR spectrometer was a flow-through gas cell, known as the light pipe (LP), delivering vapor-phase IR spectra of eluting solutes. Two other cryogenic devices which allowed mobile-phase elimination by trapping the compounds eluting from the GC at sub-ambient temperature have been developed: the matrix isolation (MI) interface operating at 11 K and the direct deposition (DD) window operating at 77 K. Each of these three types of interface has advantages and drawbacks that are discussed in terms of sensitivity and specificity. Some selected applications in selected domains of analytical chemistry, i.e. environment, flavor and fragrances, pheromones and fatty acids, are presented and discussed again in terms of sensitivity and specificity according to the interface type used. Finally some concluding remarks on technique developments for GC/FTIRS and related techniques combining chromatography with IR spectroscopy are given.

1 INTRODUCTION

Structural analysis of individual components in a complex mixture requires the coupling of separative techniques to identifications techniques, mainly spectroscopic. For volatile samples capillary GC allows the separation of most samples with high resolution, thanks to the many stationary phases commercially available. For many years, the only coupled technique available for volatile samples was GC/MS. It is one of the most widely used tools for structure determination and many areas of analytical chemistry rely upon capillary GC/MS for both qualitative and quantitative analyses. The determination of the structure of a compound from its mass spectrum can be made in several ways, the initial approach generally consisting in comparison of the experimental spectrum with existing library spectra. When the spectrum is not in any library, complete interpretation of the spectrum, sometimes helped with chemical ionization now available even on very basic benchtop instruments, is more time-consuming, and not always successful. Moreover, MS alone does not solve all the structural problems. Particularly, MS is not able to differentiate some isomers. Generations of chemists have used IR spectroscopy as a powerful tool in the analysis of molecular structures. The informative content of an IR spectrum is very high, with clear identification of chemical functions and substructures. Each molecule possesses its own characteristic IR fingerprint, and the possibility
of identifying compounds with very high accuracy by simple examination and matching of their IR spectra has been realized. Moreover, IR is particularly suited to differentiate conformational and structural isomers. Coupling GC with conventional grating IR instruments, when a spectrum takes some minutes to be acquired, was not practically feasible, despite trials essentially in the effluent stopped-flow mode.\(^1\,^2\)

Taking into consideration the numerous advantages of FTIRs over conventional dispersive IR spectroscopy, among which is the speed of analysis, the first attempts to interface a gas chromatograph to an FTIR spectrometer were made in the late 1960s,\(^1\) even though at that time, the instruments were sometimes used in the stopped-flow mode using high-capacity GC columns,\(^1,^3\) and not with on-line detection in the on-flow mode.

Since then, FTIR instrumentation has evolved considerably and compulsory computers provided extreme on-line computing power for less and less cost. State-of-the-art FTIR spectrometers are able to interface with capillary GC and to acquire IR data fast enough to accommodate the narrowest peaks obtained with high-resolution capillary GC. GC/FTIRS appears as a complementary tool to GC/MS for volatile compound identification purpose, but still represents a challenge in terms of sensitivity limits compared to this last ubiquitous technique.

Optimization of GC/FTIRS as a combined technique requires careful attention to all the component parts: GC, transfer lines to the measuring interface, the interface itself, and the IR spectrometer. Each part will be addressed in the following, but not at the same level. Only those parts specific to the technique will be developed.

HRGC using narrow-bore fused-silica wall-coated capillary columns is now standard in most analytical laboratories. Availability of stationary phases as well as capillary column dimensions adapted to a wide range of application, has made the technique widespread. Only specific comments related to the coupling to IR spectrometry will be presented.

It is beyond the scope of this article to present the basic principles of FTIRS. These principles may be found in another article, and in dedicated treatises.\(^4,^5\) Only those advantages of FTIRS over conventional grating IR spectroscopy which are relevant to the interfacing of GC will be developed.

The operating principles of GC/FTIRS coupling will be presented, with special emphasis on IR reconstructed chromatograms, IR spectra computation and the spectral library search. Finally, the main part will be devoted to the GC/IR interface. Three types are now commercially available: LP; MI; and DD. Each type has specific advantages and drawbacks, with clear impact on the technique sensitivity.

Some applications in various fields of analytical chemistry will be finally presented in order to illustrate the various interesting possibilities of the method.

2 THEORY AND OPERATING PRINCIPLES

2.1 Fourier Transform Infrared Spectrometry

An FTIR instrument used for coupling to GC is basically a single-beam FTIR spectrometer where the modulated IR beam is delivered by a rapid-scanning two-beam interferometer generally based on the original Michelson design.\(^4\) The Michelson interferometer is a device that can divide a beam of IR radiation into two paths using a beam-splitter and then recombine the two beams within a single modulated beam after a path difference has been introduced by a moving mirror (Figure 1). The interference pattern thus generated by the interferometer, the interferogram, reflects the intensity variations of the beam and can be measured as a function of path difference by an IR detector. This interferogram is the cosine Fourier transform of the spectrum of the incident radiation. As the Fourier transform is mathematically reciprocal, the IR spectrum is calculated by computing the cosine Fourier transform of the interferogram.

All rapid-scanning interferometers usually operate by signal-averaging successive scans. For precise signal-averaging, each interferogram must be sampled at exactly the same retardation delay for every scan. Therefore, very precise matching of the movable mirror is required to control the change in optical path difference. This control is obtained by the use of the interference pattern of the monochromatic light of a He–Ne laser. The sine interference pattern of the laser source, obtained either with the main interferometer or with a dedicated

![Figure 1 Schematic representation of a Michelson interferometer.](image-url)
synchronized separate reference interferometer, allows precise digitization of the IR interferogram at the zero crossings of the laser sinusoidal interferogram. Moreover, with this He–Ne laser, FTIR spectrometers have a built-in wavenumber calibration of very high precision (ca. 0.01 cm\(^{-1}\)). This is an important advantage of FTIR instruments over grating spectrophotometers known as the Connes advantage.

Other advantages with clear impacts on coupling with GC are specific to FTIRS. With FTIRS, all the spectral elements emanating from the IR source and transmitted through the sample are simultaneously received at the detector. Contrarily, with grating spectrometers where a monochromator is used, the spectral frequencies reach the detector successively. This multiplex or Felgett advantage allows a better signal-to-noise (S/N) ratio to be achieved, only proportional, at a given spectral resolution, to the square root of the measurement time, and independent of the number of measured spectral elements. The throughput or Jacquinot advantage concerns the energy range of the transmitted IR beam, which is not limited in FTIRS by the linear slits used in grating instruments to reach the desired spectral resolution. This advantage is clearly important when GC/IR interfaces may drastically attenuate the radiation throughput.

Finally, one of the main advantages of FTIR spectrometers in coupling with GC is their rapid-scanning capacity. This allows acquisition of full spectra in fractions of a second, which is mandatory for capillary GC when the duration of a GC peak is typically a few seconds. Using signal-averaging, the sensitivity is also increased as the S/N ratio, dependent on the square root of the measurement time, increases with the square root of the number of scans being signal-averaged. The last advantage often previously cited\(^5\) for FTIR instruments was the presence of a computer, compulsory for Fourier transform operations. Nowadays, with the availability of compact and inexpensive microcomputers in every analytical laboratory, this advantage can hardly be considered as specific to FTIR instrumentation.

Most of the commercially available GC interfaces are specific accessories to conventional FTIR spectrometers (Figure 2). The collimated modulated IR beam from the interferometer, normally focused at the sample point in the sample compartment, is simply directed by a removable mirror to an external port where the GC interface is connected. The only exception is the IR detector initially commercialized by Hewlett Packard as the IRD\(^{\text{TM}}\), which is a dedicated GC/FTIR instrument with optimized optics using a vapor-phase LP interface.

### 2.2 Gas Chromatography Requirements

The separation of volatile components of a complex mixture by GC is widely used by analytical chemists in various fields for both qualitative and quantitative purposes.

GC is basically a dynamic technique in which the individual components, the eluates, elute in a few seconds from the column. The dynamic range of component concentration within the sample is generally very high, the components ranging from a few tens of micrograms to a few nanograms or less. Rapid-scanning interferometers capable of acquiring a few spectra within a single second with signal averaging may accommodate the high resolution obtained with capillary GC using conventional wall-coated open tubular (WCOT) columns (0.25 or 0.32 mm internal diameter). Hence, collection of IR spectra of samples in submicrogram quantities is possible, subject to the use of an interface adapted to vapor-phase IR spectra recording.

However, since the IR response is directly related to the concentration of the sample within the GC peak, and to the presence of strong IR-absorbing chemical functions in the molecules, the best S/N ratios will be obtained for strong absorbers focused within a narrow GC peak. Optimization of the GC separation is therefore all the more necessary since the dynamic range of compound concentration within the analyzed mixture is generally very high. This implies that for any GC/IR interface using either on-the-fly detection or eluate trapping very low dead volumes must be used in order to be compatible with HRGC and to avoid peak broadening or even eluates re-mixing.

Finally, the GC column to be used in GC/FTIR applications has to be chosen in terms of sample capacity and achievable resolution.\(^5\) For standard applications with commercial interfaces, conventional WCOT columns of 0.25 or 0.32 mm internal diameter with thin film...
thickness are adequate. Chemically bonded and cross-linked stationary phases are advisable to avoid bleeding which may pollute the interface. The dynamic range of compound concentration for GC/FTIRS analysis is determined by column capacity at the upper end and by IR S/N ratio at the lower end.\(^{(7)}\)

### 2.3 Gas Chromatography/Fourier Transform Infrared Spectrometry Coupling

The potential of an FTIR spectrometer interfaced to a GC was realized soon after rapid-scanning interferometers were marketed.\(^{(6)}\) It was clear that one application for which the advantages of FTIRS should be beneficial was the on-line measurement of IR spectra of eluates from a gas chromatograph. Since then, the layout of instruments has not really changed (Figure 3), even though the cost for any individual part of this technique has dramatically dropped (this is particularly true for computers) and in the meantime their performances have been considerably improved. The GC/FTIR interface “box” will be developed later.

Passing from collected interferograms during a GC run to IR spectra of each individual GC peak requires the steps shown in Figure 4. The first step is to transform the set of collected interferograms into a reconstructed IR chromatogram. To save space on storing media, it is advisable to store only those interferograms which contain relevant spectral information. However, modern storage media may accommodate complete runs.

Basically, and theoretically, to locate the interferograms corresponding effectively to spectra of GC eluates, it is necessary to transform all the collected interferograms of the GC run into their respective spectra and then discriminate solute spectra from background. Clearly this is not of practical use for complex mixtures of several dozen peaks. Alternatively, as the presence of any IR-active chemical in the IR beam should reduce the interferogram intensity, one method consists of calculating the overall absorption power of each interferogram. In this method, analogous to the total ion current (TIC) in GC/MS, however, no reliable results are obtained, because most GC/IR absorbances are well below the practical interferogram intensity difference threshold.\(^{(8)}\) Several methods to construct or reconstruct chromatograms from interferometric data have been used to overcome these drawbacks, and some of them have been compared in terms of optimal S/N ratio and computation time.\(^{(9)}\) Among the many reconstruction methods proposed so far, two of the early described methods that construct chromatograms directly from the interferometric data are currently used.

The first of the two methods relies on the fast Fourier transform (FFT) algorithm. A spectrum is computed in real time and ratioed against a stored reference spectrum acquired before the GC run and computed at the same resolution. The integrated IR absorbance is calculated in discrete spectral regions, generally corresponding to characteristic absorptions of selected functional groups, to produce spectral window chromatograms. In the original work\(^{(6,10)}\), for evident computational limitations, five spectral windows could be defined using 32 cm\(^{-1}\) resolution spectra computed in real time from 512 data points around the centerburst of the interferograms collected as single scans at a resolution of 8 cm\(^{-1}\). With modern computers it is possible to produce several separate spectral regions or “windows” chromatograms calculated from spectra signal-averaged and computed in real time at the spectral resolution used to acquire the interferograms. These functional group chromatograms, that can be compared to single-ion monitoring (SIM) in GC/MS, are useful for identifying GC fractions belonging to a particular chemical class in complex mixtures. The S/N ratio of the functional group chromatograms may be optimized in a straightforward manner if the spectral window is defined precisely around the maxima of the absorption bands to be monitored. This is not always feasible when handling unknown samples, where it is not possible to know the most characteristic wavenumbers in advance.\(^{(5)}\) To find suitable spectral ranges for reconstructing window chromatograms, an elegant approach was developed that used spectral data representation as a contour plot.\(^{(5,11)}\) In this representation, a routine technique in two-dimensional nuclear magnetic resonance (NMR) spectrometry, the complete spectral information is plotted as contours of absorbance bands in a two-dimensional map of wavenumbers against time coordinates. Using this kind of data representation, even spectral information of overlapping peaks may be used to reconstruct very precise functional group chromatograms.\(^{(5,11)}\) The total absorbance across

![Figure 3 Schematic layout of a GC/FTIR system with the essential parts: interferometer, interface, gas chromatograph, and computer.](image_url)
the entire spectral region can be calculated to give a reconstructed chromatogram independent of the window regions that have to be chosen by the operator and where all the peaks may be observed, but at the cost of the S/N ratio.

The other method that may be used for real-time reconstruction of chromatograms directly from interferometric data is the Gram–Schmidt (GS) vector orthogonalization method developed by de Haseth and Isenhour. The GS method does not involve any Fourier transform as it relies on the multiplex nature of the interferogram: a single interferogram contains complete spectral information on absorbing samples. Therefore, a portion of the interferogram contains sufficient information to determine whether an eluate is present in the IR beam or not. In this technique, a reference set of \(x\) interferograms is collected immediately before the GC run. A small segment of each reference interferogram near the centerburst is selected. Consecutive values of the interferogram portion are treated as a vector. If \(n\) data points are chosen, they are treated as an \(n\)-dimensional vector \(I\) in hyperspace as shown in Equation (1).

\[
I = (i_1, i_2, i_3, \ldots, i_n)
\]
where \(i_1, i_2, i_3, \ldots, i_n\) are the \(n\) consecutive values of the interferogram portion, or the coordinates of the vector in the hyperspace. Using the set of \(x\) reference interferograms, a set of \(x\) orthogonal basis vectors is constructed. This set of basis vectors forms a multi-dimensional reference hyperspace and represents the background conditions, i.e. the optics characteristics when no sample eluting from the GC column is present in the light path. Each single-scan interferogram in a subsequent GC/IR run is treated in the same way as a sample vector. This sample vector can be orthogonalized and compared to the existing basis, and the absolute length of the resulting scalar from each interferogram measures the total IR absorbance of any IR active sample in the IR beam,\(^6\) i.e. refers to the quantity of eluate in the light path. To a certain extent, GS reconstructed chromatograms can be compared to TIC chromatograms in GC/MS, since each absorption band contributes to the signal. However, this must be relativized, as the signal is also dependent on the molar absorptivities of bands which tend to be much greater in the IR spectra of polar molecules than in those of nonpolar molecules.\(^6\) Optimization of GS parameters (offset from the centerburst of the interferogram, number of interferogram data points used to build the vectors, number of basis vectors in the reference hyperspace) has been the subject of specific work.\(^5\) A good compromise seems to deliver an optimum signal giving acceptable S/N ratio for the reconstructed chromatogram when 100–150 consecutive data points are selected from the interferogram in the region starting ca. 30–50 data points from the centerburst, and when approximately 10 reference vectors are included in the basis set.\(^5\) The algorithm being very rapid, GS reconstruction can be done in real time simultaneously with data collection with uncomparable sensitivity. It has also been demonstrated that GS chromatograms, the magnitude of which being dependent on the absorbance (1 minus transmittance) of the absorbing material, may be used for quantitative studies, as at the low concentrations typically used for GC/FTIR, absorbance varies linearly with compound concentration.\(^5,7\)

Despite some tentative chromatogram reconstructions with digitally filtered interferograms, leading to the selectivity of the FFT method at the computational speed of the GS method,\(^12\) and with claimed advantages on combined selectivity, S/N ratio and computational speed, the GS method remains the standard method to reconstruct total IR chromatograms. Once a reconstructed IR chromatogram has been computed from interferometric data using any reconstruction method, it is necessary to produce an interpretable IR spectrum for each peak in the mixture. This is generally done as illustrated in Figure 4. A single-beam background spectrum showing characteristics of optics, interface and detector is calculated from a region of the chromatogram where no compound is eluting, preferably not too far from a peak of interest. A single-beam sample spectrum is obtained from the interferometric data corresponding to an eluate, generally by co-adding several interferograms within the chromatographic peak, before applying FFT. Each saved interferogram is the result of the co-addition of a few (four to five) single interferograms, for signal-averaging and S/N ratio purposes.

The final transmittance or absorbance (−log transmittance) spectrum is calculated by ratioing the single-beam spectra. If the database spectral search is to be carried out on experimental spectra, the data must be expressed as absorbance spectra.

2.3.1 Spectral Resolution

The spectral resolution in FTIRS depends on retardation, or optical pathlength difference. Namely, to resolve two spectral lines separated by a distance \(\Delta \nu\) cm\(^{-1}\), the retardation \(\delta\) cm should at least be \(\delta = (\Delta \nu)^{-1}\), and if the maximum retardation of an interferometer is \(\Delta_{\text{max}}\), the best spectral resolution achievable with this interferometer is \(\Delta \nu = (\Delta_{\text{max}})^{-1}\). Increasing the resolution, i.e. increasing the retardation, results in increasing measurement time. Clearly, in GC/FTIR coupling, the measurement time cannot be extended too much and the optimum one is determined by the elution duration of a GC peak for on-the-fly detection, taking into account signal-averaging constraints. To improve the precision of band maximum determination and photometric accuracy, interpolated points may be added in the spectrum by extending the interferogram data points with zeros before computing. This zero filling procedure (one level of zero filling doubles the file size for Fourier transformation) increases the digital resolution of the spectrum without introducing any error itself, as the raw data and the instrumental line shape are not affected. For most of the GC/IR analytical problems, a spectral resolution of 8 cm\(^{-1}\) and one level of zero filling before FFT seem an acceptable working compromise.\(^5\) For specific needs, a higher spectral resolution may be used (i.e. 4 cm\(^{-1}\)) but at the cost of decreased S/N ratio when the measurement time cannot be increased.\(^5\)

3 THE GAS CHROMATOGRAPHY/FOURIER TRANSFORM INFRARED INTERFACES

An important breakthrough for FTIRS, which partly explains the rapid developments of GC/FTIR coupling, was the introduction of the narrow-range mercury cadmium telluride (MCT) photodetector cooled to liquid
nitrogen temperature. The specific detectivity of this detector is more than an order of magnitude greater than that of the standard deuterated triglycine sulfate (DTGS) pyroelectric bolometer supplied with most commercial FTIR spectrometers. Moreover, the MCT photodetector accommodates the high modulation frequencies necessary for GC/FTIRS, when the DTGS response decreases with increasing interferogram modulation frequency.\textsuperscript{[4,5]} The first demonstration of GC/FTIRS was effective soon after the commercial achievement of rapid-scanning interferometers. Thus Low and Freeman\textsuperscript{[13]} reported on-the-fly IR detection of GC eluates from a packed column using a small flow-through gas cell (ca. 0.6 mL volume) placed between the source and the interferometer.\textsuperscript{[13]} Soon after, the first GC/FTIR accessory, consisting of a gas cell that fitted inside the spectrometer sample compartment, collected interferograms for packed column chromatography using either flow-through or trapped (stop-flow) modes.\textsuperscript{[4]} In 1974 Azarraga and McCall (cited by Griffiths and de Haseth\textsuperscript{[4]}) showed that capillary GC/FTIRS could be performed using a support-coated open tubular column with on-the-fly sampling using the gas cell (or LP) GC/IR accessory. A major breakthrough was the development of gold-coated borosilicate glass LPs by Azarraga.\textsuperscript{[14]} These LPs were constructed to have a very high transmittance and they allowed the coupling of WCOT columns.\textsuperscript{[15]} Today, most FTIR vendors propose optimized LP accessories for GC/FTIR coupling to fused-silica WCOT GC columns.

3.1 The Light Pipe

A typical arrangement for a GC/FTIR system using a LP interface is represented schematically in Figure 5. Clearly, the interface has to be optimized from both chromatographic and spectrometric points of view. In a typical GC/IR measurement the effluent from the GC column is passed through a heated transfer line continuously to a heated measuring gas cell, the LP. Meanwhile, the modulated IR beam collimated through an external port of the interferometer is focused to an IR-transparent window at the entrance of the LP. The radiation containing information of absorbing material within the effluent exiting from the LP is focused onto the MCT detector element. The effluent getting out of the LP may be directed, through another heated transfer line, to a conventional GC detector, as IR detection is nondestructive.

The LP (Figure 6) is essentially a gold-coated glass tube. The gold coating allows the IR beam to undergo multiple reflections in order to enhance the overall optical throughput of the cell. This material is assumed to be chemically inert, remarkably resistant and stable, an important advantage for a material that must be necessarily heated and that should be chromatographically inert. The high temperature of the LP is however a problem as a large decrease in signal intensity occurs...
with increasing temperature. This effect results from high levels of unmodulated IR radiation emitted from the hot LP, this being an IR radiator itself, radiation which saturates the detector or its associated preamplifier.\(^{(16)}\)

Using a cold shield positioned at the end of the LP eliminates the emission from the hot LP.\(^{(16)}\) However, it was then demonstrated that the same improvement may be obtained by using a simple optimized optical configuration where the IR beam exiting the LP is precisely focused on the detector element.\(^{(17)}\) Practically, the temperature of the LP will be normally dictated by the upper temperature used in the GC analysis.\(^{(5)}\)

From the GC point of view, the LP and transfer lines are dead volumes, especially when using narrow-bore GC columns. Generally, the column or fused-silica tubing is fed through the heated transfer lines up to the entrance and the exit of the LP in order to have a virtually zero dead volume. The size and geometry of the LP have been the subject of theoretical studies.\(^{(4)}\) Clearly the length, inner diameter and length-to-diameter ratio are critical factors in achieving good S/N ratios in the resulting spectra. Ideally, the volume of the LP, \(V_{\text{cell}}\), should not exceed the volume of carrier gas between the half-height points, \(V_{1/2}\), of the narrowest peak in the chromatogram\(^{(4,6,18)}\) to avoid a severe degradation of the GC resolution. Obviously this requirement cannot be fulfilled in every circumstance, and the practical LP volume should be a compromise between optical throughput and chromatographic considerations. A reasonable choice will depend on the most frequently used column type.\(^{(5)}\) For narrow-bore fused-silica columns cell volumes between 50 and 150 \(\mu\)L are typical, and adding make-up gas could be advantageous when the volume of the LP exceeds the volume of the GC peaks. A comprehensive review of the hardware from transfer lines to optics, including sampling considerations, may be found in a specialized treatise.\(^{(4)}\) Some practical information may be found in a monograph by Herres.\(^{(5)}\) The sensitivity of the LP interface in terms of detection limits is in the nanogram range. Even though some studies report detection limits at the subnanogram level, it should be assumed that it was achieved only for exceptionally strong absorbing analytes. Moreover, as already outlined in 1984 by Cooper and Taylor,\(^{(19)}\) published detection limits do not reflect the amount of material required for a positive identification, especially when spectral search identification is being used. The “practical” limit of detection/identification is in the tens of nanograms range for compounds that are good IR absorbers and fairly volatile. This limit is clearly higher for poor absorbers and less volatile compounds. This limit seems the threshold limit obtainable with an LP system, even with carefully optimized optics,\(^{(17)}\) as no significant improvement has been made since the development of LP interfaces adapted to narrow-bore fused-silica WCOT.

\[
\begin{align*}
\text{Absorbance} & = \frac{I_0 - I}{I_0} \\
& \approx -\log \left( \frac{I_0}{I} \right) \\
& = -\log \left( \frac{I_0}{I_0 - I} \right)
\end{align*}
\]

\(I_0\) and \(I\) are the IR intensities of the sample at the entrance and exit of the LP, respectively.

### 3.2 The Matrix Isolation Technique

As outlined above, even an optimized LP system is not sensitive enough to solve all the problems amenable to HRGC and HRGC/MS. One possible way to gain substantial sensitivity, that is to enhance the S/N ratio, is to raise the sample absorbance and to lengthen the observation time per sample. This could be achieved by means of cold trapping the components using a suitable trap capable of freezing out highly volatile compounds, followed by off-line IR measurement with extensive signal-averaging if necessary. This can be done by using a technique known as MI.

The MI technique has been extensively used to study detailed spectrometric properties of a large variety of molecules, free radicals and ions.\(^{(4)}\) In this technique, the molecules under investigation are co-condensed on a spectroscopically transparent window or an IR-reflecting surface with a large excess of an inert and IR-transparent gas, such as argon, at cryogenic temperatures (below 20 K) under vacuum. Trapped and diluted in a solid matrix at these temperatures, the individual molecules do not interact with each other and the molecular rotational motion is absent. As a consequence, IR absorption bands sharpen significantly, and even small shifts and band splitting may occur.

Early work demonstrated the feasibility of coupling GC to MI/FTIR,\(^{(24–26)}\) although these original interfaces suffered from the same problem of insufficient focusing of the GC eluate on the cryogenic surface, precluding any significant gain in sensitivity. An optimized version
was described in 1985\(^{(27)}\) with claimed sensitivity in the 100 pg range, giving rise to a commercial GC/MI/FTIR instrument, known as the Cryolect\(^{\text{TM}}\), the interface being developed by the Cryolect\(^{\text{TM}}\) Scientific Corp., and available at that time from Mattson Instruments. In this system, presented schematically in Figure 8, the cryogenic surface was the gold-plated mirrored surface of a rotating cryogenic disk or “cryodisk”. The cryodisk was placed in a vacuum chamber and maintained at a temperature of 11 K by a closed cycle helium refrigerator which did not require the use of liquid helium. The sample inlet port and the IR beam port were found on opposite sides, facing the curved surface of the cryodisk. The sample inlet port was a capillary tube passing through a copper block and a metal nozzle sealed into a Pyrex window. The end of the capillary tube protruded slightly from the nozzle. The Pyrex window and attached binocular microscope allowed observation of the nozzle and capillary tip, so that the position of the latter could be precisely adjusted with respect to the surface of the cryodisk. For IR data collection, a pair of off-axis paraboloid mirrors (M2 and M4 in Figure 8) were mounted outside the vacuum chamber. The first one focused a collimated IR beam coming from a FTIR spectrometer onto the mirrored surface (M3) of the cryodisk through a thin fused KCl window. In reflecting from the mirrored surface M3, the IR beam passed twice through condensed material and was redirected and collimated by mirror M4 towards a MCT IR detector. Figure 9 displays an enlarged view of the sample collection surface. Fused-silica capillary tubing, 150 µm in diameter and separated by 150 µm from the collection surface, protruding slightly beyond the heated nozzle, directed the GC effluent against the mirrored surface of the cryodisk. The helium carrier gas, noncondensable at the working temperature and eliminated in vacuo, was balanced with 2% argon. The argon and sample molecules formed a solid layer on the cold surface. The eluates from the chromatograph were retained in sequence in the track of frozen argon on the surface of the rotating cryodisk. Each collected compound was contained within an area typically 0.3 mm in diameter yielding a high level of spectral absorbance per mass unit of sample. Measurement of IR spectra by specular reflectance from the metallic surface was made by rotating the cryodisk after deposition was completed so that the portion of the solid argon matrix that contained components of interest was placed at the focus of the IR beam. Computer-controlled disk motion facilitated this operation, as did retention time data obtained with the flame ionization detector (FID) of the GC by dividing the
GC effluent in two parts, but GC/MI/FTIRS using this interface could not be considered as a real-time technique, as post-GC run operation was necessary. However, once a compound was deposited, extensive signal-averaging could be done if necessary to enhance the S/N ratio of spectra obtained for diluted samples or poorly absorbing molecules. The deposited compounds were removed from the cryogenic sample collector by warming it up after completion of the data collection.

These results demonstrated the achievement of MI of molecules eluting from a high-resolution gas chromatograph without any loss of separation power. The gain in sensitivity was estimated to attain a factor between 10 and 100 compared with LP GC/FTIR. The GC/MI/FTIR sensitivity was found to be quite similar to the current GC/MS sensitivity (i.e. low nanogram range). Both detection modes were implemented in parallel on some Mattson-Cryolect commercial instruments by dividing the effluent from the GC into two parts. This rendered the instrument highly efficient with two compatible and highly complementary identification techniques. Figure 10 shows an example of MI spectra obtained in the original work with ca. 60 ng of dioxin samples.

Specificity of MI IR spectra, particularly sharp absorption bands, is due to the absence of band broadening following molecular rotation or intermolecular interaction. These spectra can be considered as pure IR vibrational spectra. This specificity allows straightforward discrimination among closely related isomers, discrimination simply impossible to achieve with the LP interface, or even with traditional IR spectra obtained in the condensed phase.

The major disadvantages of the GC/MI/FTIR technique are its complexity, the hardware being more sophisticated and requiring more precise construction than the LP interface, and its higher cost. Moreover, the MI interface requires intensive training to maintain and operate, particularly for the optical bench alignment procedures. Another drawback is that argon matrix spectra are different from the conventional spectra obtained in condensed phase and also different from gas-phase spectra. Moreover no commercial library is available with spectra acquired under these conditions. However, spectral specificity with subsequent unparalleled identification power, sensitivity enhancements due to the concentration of the analyte, extensive signal averaging and peak sharpening, and complete compatibility with demanding high-resolution capillary GC are unique features of the MI interface. Unfortunately, for some years the Mattson-Cryolect instrument has not been commercially available. A new instrument (vide infra) is available in the US, the MI-TREK commercialized by Reedy Scientific Instruments (Bourbonnais, IL).

A major drawback of MI technology is that it operates at the very low temperature of 12 K. Efforts have been made in order to increase the working temperature to the liquid nitrogen temperature using matrixless deposition of eluates at 77 K or MI in xenon at 65 K. Subambient temperatures (−10 to −45 °C) have also been investigated using eluate trapping on an IR-transparent window moved to the focal plane of an FTIR microscope which allowed IR data collection shortly after the eluate was deposited. By placing the IR-transparent window in a vacuum chamber and adapting the optics, it was possible to obtain IR transmission spectra of eluates trapped at the liquid nitrogen temperature (77 K) in “pseudo real time” with subnanogram sensitivity. This work was the basis for the development of a commercial real-time DD interface for GC/FTIRS.

3.3 The Direct Deposition Interface

Performance characteristics of the DD interface commercialized by Bio-Rad Laboratories as the Tracer GC/IR interface were described by Bourne et al. in 1990. A schematic of the optics, sample collection device and
the layout of the commercial instrument is presented in Figure 11. The sample slide, mounted on a copper cold-block, is a rectangular ZnSe window transparent to the IR. This assembly is mounted on a motorized XY stage inside a vacuum chamber maintained at 10⁻⁵ Torr by a turbomolecular pump. The ZnSe window is cooled with flexible thermal transfer lines placed between the moving cold-block and a liquid nitrogen reservoir (Figure 11). With this arrangement the temperature of the window never exceeds 97 K.⁴³ The heated transfer line from the GC incorporates an orifice of 50 µm internal diameter positioned 50 µm from the surface of the window, close to the focus point of the IR beam. The analytes in the effluent are deposited on the window as small frozen spots of approximately 100 µm width. The window is moved continuously step by step, and each spot passes through the IR beam just after a short time delay, making the technique a “quasi” real-time one (Figure 11). The IR beam is transmitted through the sample and window, and collected for transmission to an MCT detector by a Schwartzchild microscope attachment. As the position and movement of the ZnSe window are under computer control, the spectra are recorded by computer control, the spectra are recorded by computer and the sample is moved to the next point.

**Figure 11** Layout of the commercial DD GC/FTIR interface (Tracer™) with eluate deposition scheme. (Reproduced by permission of Bio-Rad SA.)

**Figure 12** GC/DD/FTIR real-time spectrum of ca. 50 ng of 2-hexanone present in a complex mixture of volatile compounds.
control, the window may be repositioned for post-run IR measurements with extended signal-averaging for improved S/N ratios, as they are with the MI system. The IR spectra are obtained in the condensed (solid) phase, in the traditional transmittance mode. An example is presented in Figure 12. It has been demonstrated that DD spectra may be directly searched against conventional libraries of IR spectra of reference materials prepared as KBr disks. Low subnanogram sensitivity down to a few tens of picograms has been demonstrated with this GC/DD/FTIR interface for a variety of chemicals with real-time measurement.

3.4 Gas Chromatography/Fourier Transform Infrared Spectra and Sensitivity

The three different GC/IR interfaces based on three different principles lead to different IR spectra. The heated LP interface, the MI cryogenic system and the DD device give gas-phase, matrix-isolated and solid-phase spectra, respectively. This implies that the different spectra acquired in the different modes are significantly different in terms of absorption band intensity and width, and in terms of band position. A shift to higher frequencies is noticed on changing from solid to liquid to gaseous state. This change is accompanied by a general narrowing and an intensity decrease for the bands involved in hydrogen bonding in the condensed phase. Gas-phase spectra give broad absorption bands due to enhanced rotational motion in the heated LP. For important characteristic bands that could be weak, this is particularly a handicap. On the other hand, solid-phase spectra obtained with the DD interface give rise to sharper and more intense bands. For comparison purposes, Figure 13 shows the IR spectra of a C_{18:1} unsaturated fatty acid methyl ester possessing a trans double bond, methyl elaidate. The position of the main absorption bands (C=H stretching and carbonyl stretching) are different, shifted towards lower frequencies by ca. 10 cm\(^{-1}\) for C=H stretching from 2933 in the gas phase to 2923 cm\(^{-1}\) in the solid and 20 cm\(^{-1}\) for the C=O stretching from 1759 in the vapor phase to 1739 cm\(^{-1}\) in the solid state. The respective ratios between these bands are also clearly different. On the contrary, the C=H out-of-plane deformation band, characteristic of the trans double bond, is found at the same wavenumber (968–969 cm\(^{-1}\)) for both modes but with a clear advantage for the solid-state spectrum from the intensity standpoint. (This characteristic band which appears invariant is found at the same position around 970 cm\(^{-1}\) in MI spectra.)

MI spectra are different from both gas-phase and solid-state spectra. As already outlined, they are pure vibrational spectra, resulting with sharp absorption bands. Practically, as it is shown in Figure 14, they can be considered as intermediates between gas-phase spectra (in terms of band position) and solid-phase spectra (in terms of band intensity). For instance, the matrix isolated spectrum of a conjugated trans,trans-C_{18:2} diunsaturated fatty acid methyl ester displays C=H and carbonyl stretchings at 2935 and 1754 cm\(^{-1}\), respectively, close to the corresponding gas-phase features, but the respective intensities are those of the solid-state spectrum (Figure 14b) in which however the bands are found at lower frequencies (2923 and 1739 cm\(^{-1}\) respectively). On the other hand, the C=H out-of-plane deformation band, characteristic of the conjugated trans,trans configuration, is found at exactly the same frequency (990 cm\(^{-1}\)) with comparable relative intensities.

Another structural feature worth mentioning here is the hydroxyl stretching vibration of alcohols. As in the solid phase obtained with the DD interface intermolecular forces such as hydrogen bonding are present, the OH stretching bands are significantly broadened, as they are with KBr disks or neat films. Therefore the OH stretching band appears as a very broad band between 3500 and 3000 cm\(^{-1}\) (Figure 15). MI spectra of alcohols display intense and sharp absorption bands for the OH
Another example of the importance of such an observation, a unique feature of gas-phase IR spectra of alcohols, will be presented below (see section 4.3).

As already outlined, only the cryogenic interfaces such as the MI or DD devices possess intrinsic sensitivity fully compatible with demanding GC analyses that can be easily handled by GC/MS. This has been fully documented (see Le Quéré and Sémon(22) for example). Very low detection limits (to the picogram range) have been published for both cryogenic interfaces,28,33 but these limits have been obtained with extensive signal-averaging in post-GC runs, and not on a regular routine basis. Nevertheless the cryogenic interfaces have a detection limit of one or two orders of magnitude lower than that of the LP interface. For the latter, it seems that no significant improvement should be obtained, due to the technique itself.

One of the claimed advantages of the DD interface is that the spectra obtained in the solid state may be searched in conventional IR spectral libraries, where spectra are generally obtained as KBr disks.33 Spectra obtained by this interface are characteristic of a solid-phase sample in an amorphous state. However some typical crystalline features such as band splitting and fringing effects can be noticed. Significant differences between the two types of spectra could be observed, and some bands, like the carbonyl ones, are shifted at lower frequencies by about 10 cm⁻¹ for solid-state spectra obtained at cryogenic temperature.38 Moreover, water introduced into the system either by the sample or as a result of poor conditioning gives solid ice on the window, which results in band broadening. It appears necessary to dry the chamber under vacuum for 1 day after opening it to the atmosphere for routine maintenance.38 In their original work, Bourne et al.33 demonstrated the possibility of searching a vapor-phase library for nonpolar compounds such as chlorinated pesticides when only the fingerprint region is included for the search. However when the analytes contain some moieties that may be involved in intermolecular interactions such as hydrogen bonding, it is advisable to use a database for spectral searching where the reference materials are in a similar state to the unknown analytes.33

Vapor-phase reference spectra are available in various libraries such as the Environmental Protection Agency library of vapor-phase IR spectra, the Sadler–Heyden spectra,36 the Aldrich library of FTIR spectra39 and the Sadler vapor-phase IR database (Bio-Rad Laboratories, Sadtler Division). To our knowledge, no MI reference spectral library is commercially available. Table 1 summarizes a comparison of the characteristics of the three techniques discussed in this paragraph.

GAS CHROMATOGRAPHY/INFRARED SPECTROSCOPY

4 SOME APPLICATIONS OF GAS CHROMATOGRAPHY/FOURIER TRANSFORM INFRARED SPECTROMETRY

It is beyond the scope of this article to give an exhaustive overview of the applications of GC/FTIR in analytical chemistry. In fact, all the problems amenable to GC may use FTIR as a powerful detector. However in order to illustrate the capabilities of the technique, some selected examples from selected domains will be presented. An early comprehensive review may be found in a specialized treatise and dedicated contributions appear periodically in specialty journals.

4.1 Environmental

Substantial efforts have been made to apply GC/FTIRS for qualitative and quantitative environmental analysis of typical environmental contaminants. The claimed advantages were specificity and selectivity, IR being able to distinguish between isomers, and the complementary nature of GC/FTIRS and GC/MS was soon acknowledged. Efforts made to improve the performance of GC/FTIR interfaces, particularly the LP interface, were very often motivated by environmental issues (see Gurka et al. for example). This system finally exhibited minimum identifiable quantities in the 10–50 ng range for standards, soil samples and a herbicide still-bottom. Quantitative capabilities of GC/FTIRS were also clearly demonstrated for priority pollutants.

Cryogenic GC/IR interfaces showed improved sensitivity: minimum identifiable quantities ranged from 0.5 to 2 ng in one study on polynuclear aromatic hydrocarbons and pesticides using the DD interface. As an example Figure 16 shows the GC/FTIR spectrum of 2 ng DDT (dichlorodiphenyltrichloroethane) obtained on-the-fly with this interface. A sensitivity down to 100 pg has been demonstrated with this interface for on-the-fly detection of hexachlorobenzene. A picogram level quantitation of 2,3,7,8-tetrachlorodibenzo-p-dioxin in fish extracts has also been reported for the MI interface.

4.2 Flavor and Fragrances

Identification of flavor and fragrance molecules is a major field of application for GC/IR. The complementary nature of GC/IR and GC/MS for the structural analysis of volatile flavor compounds was recognized very early on, with particular emphasis on the unique ability of IR spectroscopy to distinguish individual isomers. The early literature through to the end of 1985 has been covered, with applications to the aroma composition of tropical fruits, alcoholic beverages and the volatiles emanating from intact fruits of Coffea arabica. The technique has been demonstrated to be very powerful for the analyses of essential oils, and especially for the structural investigation of terpenes and sesquiterpenes where unequivocal identification by MS alone is very often difficult and when FTIR delivers spectra with clear fingerprints. Recent investigations used the DD interface for increased specificity and sensitivity, where IR spectra matched the documented literature spectra obtained as liquid or KBr pellets. The usefulness of the MI technique for the analyses of flavor extracts has also been demonstrated.

In flavor research coupled GC/FTIRS in conjunction with GC/MS is now a routine tool for characterizing the structure of the volatile components. The LP system is very often chosen for its ruggedness and low cost, even though the cryofocusing devices present an intrinsic sensitivity one or two orders of magnitude lower.

4.3 Pheromones

Insect pheromones or plant-emitted substances involved in insect–plant interaction are other volatile components that have benefited from the complementary nature of GC/MS and GC/FTIRS. Recent work in the domain uses the sensitivity advantage of the DD interface and coupling with solid-phase microextraction (SPME) adds some advantages. However, a lot of results have been obtained in the vapor phase with the LP interface. Figure 17 shows the IR spectrum of a female-specific compound isolated from the tergal gland secretion of a primitive cockroach Cryptocercus punctulatus. This primitive woodroach lives in galleries in rotten wood and it is the best living representative of the ancestral blattarian-isopteran stock. Besides, several aspects of its life and morphology...
strongly resemble the termites\textsuperscript{(64)} and a better knowledge of its biology is of fundamental interest.

The IR spectrum confirmed the presence of a hydroxyl group in the pheromonal compound, the OH stretching frequency (3668 cm\textsuperscript{-1}) falling in the range of secondary alcohols.\textsuperscript{(36)} Another stretching frequency (3605 cm\textsuperscript{-1}) revealed intramolecular hydrogen bonding, probably resulting from the interaction of one of the carbon–carbon unsaturations present in the molecule, via a (5 + π) intramolecular hydrogen-bonded system.\textsuperscript{(30)} This feature, unique to vapor-phase spectra as already outlined, fixes the position of the hydroxyl group relative to the carbon–carbon double bond, and is therefore highly structurally informative. The medium absorption at 960 cm\textsuperscript{-1} was attributed to a CH out-of-plane deformation of a trans disubstituted ethylenic bond. These data greatly helped to propose the structure \textit{4,6,8-trimethyl-7,9-un-decadien-5-ol} for the pheromonal compound.\textsuperscript{(64)} This hypothesis was confirmed later with the synthetic compound.

### 4.4 Fatty Acids

IR spectroscopy has long been used as a dedicated method to distinguish between cis and trans isomers and to determine the total amount of trans fatty acids in fats and oils. The IR analysis of individual isomers in complex mixtures of unsaturated fatty acids was made possible through the combined GC/FTIR technique. The first example published in the literature described the analysis of unsaturated cyclic fatty acid mixtures isolated from heated oils using an LP interface.\textsuperscript{(68)} This interface type was extensively used to characterize geometrical isomers of polyunsaturated fatty acids (PUFAs) in various applications.\textsuperscript{(69,70)} However, it was soon recognized that greater instrumental sensitivity compatible with HRGC was required to determine the minor components found in mixtures with extremely unbalanced dynamic range of concentration (i.e. levels of minor components such as trans PUFAs less than 1%). In this respect, the MI interface was successfully used by Mossoba et al.\textsuperscript{(55,71)} Examples of characteristic spectra have already been presented above. More recently, it has been demonstrated that the DD interface is also particularly well suited to the study of complex fatty acid mixtures.\textsuperscript{(72)}

### 5 PERSPECTIVE

GC/FTIRS is a valuable tool for the analytical chemist whose main concern is the structural determination of volatile compounds or any component that can be separated by GC. LP technology has reached a standard of achievement limited in terms of sensitivity and specificity, but still very useful and easy to use and maintain. The cryogenic effluent-trapping techniques, i.e. MI and DD, despite their intrinsic sensitivity are not common instruments in analytical laboratories, probably due to their cost and to their inherent sophistication. The MI Cryolect\textsuperscript{™}-Mattson instrument has not been available for some years, and, to our knowledge, the DD Tracer\textsuperscript{™} Bio-Rad instrument is no longer commercially available. A new MI system appeared recently, the MI-TREK\textsuperscript{™} (Reedy Scientific Instruments, Bourbonnais, IL), for which a comprehensive review has been published.\textsuperscript{(71)} Based on the original design (vide supra), the MI-TREK\textsuperscript{™} has however distinct advantages that will be depicted in the following text.

The interface between the IR spectrometer and the GC is a compact vacuum chamber containing the sample collector and the optics necessary to focus the IR beam on the surface of the collector (Figure 18). The IR beam coming from the interferometer is deflected by a plane mirror to enter the vacuum chamber. Within this vacuum chamber it reflects from a plane mirror towards the first of twin paraboloidal mirrors attached to a single block of aluminum. The two paraboloids have a common focus on the mirrored surface of the collector where the samples are matrix-isolated. The IR beam reflects to the second twin mirror, and then the beam is collimated to the paraboloid mirror at the detector. Contrarily to the original design, the collector disk is in a vertical position (Figure 19). It rotates counter-clockwise during sample collection. This arrangement allows the collection surface where the samples are trapped in a layer of argon matrix to move from the “sample delivery point” to the “IR scan point” within a short delay, making the technique a “pseudo real-time” one like the DD interface. Cooling for the cryogenic surface is provided by a closed-cycle helium refrigeration system which requires no liquid helium.
The refrigerator provides two stages within the vacuum chamber. The first stage operates at 50 K and provides cooling for a reflector shield (Figure 19) which reflects environmental radiant heat and collects background gases such as H₂O and CO₂. The sample collector itself is supported and cooled by the second stage of the refrigerator operating at 10 K. The MI-TREK™ system has been designed to incorporate parallel MS detection by dividing the GC effluent in two parts, with ca. 25% directed to the MS detector. The intrinsic sensitivity of the cryogenic GC/IR interface makes this double-hyphenated technique useful. In fact, all the cryogenic interfaces operating under vacuum are fully compatible with MS, which also operates under vacuum. However simultaneous detection is only possible by dividing the GC effluent in two parts. Contrarily, as the LP system allows on-the-fly IR detection, it is possible to attach an MS detector at the exit of the LP. But as the MS detector is far more sensitive than the IR one, it is also necessary to split the GC effluent (ca. 1/14) to the MS. Many efforts have been made to develop GC/FTIR/MS systems, but this double-hyphenated technique is not widespread despite its potential.

Among the technical developments on the combination of chromatography and FTIR spectrometry, the coupling of high-performance liquid chromatography (HPLC) and supercritical fluid chromatography (SFC) to a FTIR spectrometer has received considerable attention. Specific problems related to mobile phases used in HPLC arose with HPLC/FTIRS: no solvent used within the mobile phases is transparent to IR radiation. The use of a flow cell interface necessitates a limitation of the pathlength, resulting in a significant limitation on the sensitivity. Several approaches to eliminate the solvent prior to the IR measurement have been described and subnanogram detection limits have been reported even for reversed-phase HPLC/FTIR using a DD interface. Like GC/FTIRS and HPLC/FTIRS, both flow cell and mobile-phase elimination devices have been described for SFC/FTIRS. Despite the fact that flow cell must accommodate very high pressures, many results have been obtained with this technology, essentially because the transmittance of supercritical CO₂, the most popular fluid used for SFC, is significantly greater than that of most HPLC mobile phases. The method was successfully applied in various fields such

as flavor research\textsuperscript{77,78} lipids\textsuperscript{79} with the benefit of analyzing free fatty acids and triglycerides using the same chromatographic column\textsuperscript{80} monosaccharides, mycotoxins and food additives\textsuperscript{71} Despite significant sensitivity improvements that have been obtained with flow cells (see Wieboldt et al.\textsuperscript{81} for example), subnanogram detection limits have been only achieved with a DD interface that eliminates the supercritical mobile phase\textsuperscript{75} On-line SFC/DD/FTIR spectra have been obtained by slightly modifying the DD device used for GC/FTIR, using a window temperature close to room temperature\textsuperscript{75} Excellent results have been obtained with this technique in the analysis of poly(ethylene glycol)s of various average molecular weights\textsuperscript{45} In this mode, as with the GC/DD/FTIR interface, the spectra are obtained in the condensed state, and they may be searched against a conventional IR spectral database.

In conclusion, after this short overview of technique developments, it is clear that the use of FTIR provides sensitive detection of species eluting from a gas chromatograph, and delivers positive identification through the observation of characteristic spectral information. In particular, GC/FTIRS is able to differentiate closely related isomers, a unique feature of IR spectroscopy. Therefore, in analyzing volatile or semi-volatile compounds, GC/FTIR appears to be an essential complement to GC/MS.

**ACKNOWLEDGMENTS**

The Institut National de la Recherche Agronomique (INRA) and the Conseil Régional de Bourgogne are thanked for financial support. The author is indebted to Christian Giniès and Etienne Sémon for skillful operation of the GC/FTIR instruments at INRA, Laboratoire de Recherches sur les Arômes, and for interesting discussion.

GAS CHROMATOGRAPHY/INFRARED SPECTROSCOPY

Infrared reflection–absorption spectroscopy (IRAS, IRRAS) is an optical technique used to study thin (often submonolayer) films adsorbed on reflective substrates such as metals. Experimentally, it involves measuring the change in the reflectance spectrum of the substrate that accompanies adsorption. In order to maximize sensitivity, the reflection is usually performed at grazing incidence. On metal surfaces, the process is subject to an overriding selection rule which states that only those vibrational modes that have a component of their dipole change perpendicular to the surface can be detected: application of this metal surface selection rule (MSSR) often yields important information about adsorption geometry. Other advantages of the technique include its high sensitivity (<10⁻⁴ monolayers in favorable instances), its ability to operate under high ambient pressures where other primarily electron-based surface spectroscopies cannot be utilized, and the ease with which its results can be correlated with those from other vibrational spectroscopies, both surface- and bulk-sensitive. A significant current disadvantage is the difficulty in studying low-wavenumber vibrations, but this is being overcome by the development of more intense far-infrared sources. Various acronyms for the technique have been employed – IRAS, IRRAS and Reflection–Absorption Infrared Spectroscopy (RAIRS) have all enjoyed wide currency. The last of these is perhaps the most widely used and is the form advocated by the International Union of Pure and Applied Chemistry (IUPAC).(1,2) Accordingly, it will be adopted in this article.

1 INTRODUCTION AND HISTORICAL OVERVIEW

The first applications of infrared spectroscopy to the study of adsorbed species date back to the late 1930s and its use to characterize supported catalysts had become well established by 1960. However, these early studies employed powdered or porous substrates with high specific areas, typically between 1 and 1000 m² g⁻¹, which allowed milligram quantities of the adsorbed species to be introduced into the infrared beam. The 1960s witnessed the rapid development of a range of surface science probes capable of determining adsorbate structures and electronic energy levels on single-crystal and other well-defined substrates, thereby emphasizing the need for complementary techniques of vibrational spectroscopy in this area. The rather small surface area of the samples employed in surface science (∼10⁻⁴ m²) corresponds to only nanogram masses of adsorbate in a monolayer, so sensitivity poses a much more severe problem than in the study of high area materials. Despite this, infrared sensitivity to monolayer quantities was quickly attained, initially by Pickering and Eckstrom, who studied the adsorption of carbon monoxide and hydrogen on nickel and rhodium films using a multiple reflection procedure in which the incoming beam was at near-normal incidence to the surface. That such a geometry was far from optimum was recognized by Greenler,(4,5) who developed the underlying theory of RAIRS which will be described in the next section, demonstrating that sensitivity was optimized at high angles of incidence. Subsequent studies have employed glancing incidence beams, almost always using a single-reflection configuration. The first characterization of an adsorbate on a single-crystal substrate was achieved in Pritchard’s laboratory at the end of the 1960s.(6) This group also pioneered the integration of RAIRS with other techniques of surface science such as low-energy electron diffraction, surface potential measurements, and various electron spectroscopies. This trend has continued and it is now normal for RAIRS instrumentation to be integrated into a system that also contains other probes to establish surface composition, structure, and topography.

Until the mid-1980s, specialized dispersive spectrometers were almost invariably used for RAIRS. Excellent signal-to-noise (S/N) ratios could be achieved over a limited wavenumber range with such instruments (corresponding to a sensitivity of less than a thousandth of a monolayer for a strongly absorbing species such as carbon monoxide). However, dispersive spectrometers are...
poorly suited to rapid scanning of broad ranges of the infrared spectrum, while the specialized nature of the instruments employed in RAIRS discouraged its wider application. The use of commercial Fourier transform infrared (FTIR) spectrometers in RAIRS studies was pioneered by Chesters, who clearly demonstrated their advantages over dispersive spectrometers, and FTIR instrumentation is now almost universally employed. Recent developments in RAIRS have concentrated on extending the range of application of the technique: important instances of this include extension of the wavenumber range (especially into the far-infrared, to observe vibrations of the primary chemisorptive bond between surface and adsorbate), the use of higher gas pressures to mimic industrial catalytic processes, and even studies in aqueous environments, particularly in the study of electrode reactions.

2 PRINCIPLES

The process of reflection at a surface is most easily analyzed by considering the behavior of two polarization components, the $s$ component, whose electric field is polarized parallel to the surface and perpendicular to the direction of propagation, and the $p$ component, perpendicular to both the $s$ component and the line of propagation (Figure 1). Radiation of arbitrary polarization can, of course, be resolved into a combination of these two components.

The process of reflection changes both the magnitude and the direction of the electric field associated with each of these components. A molecule in the vicinity of the surface thus experiences a combination (i.e. the vector sum) of the fields due to the incident and reflected beams. With metals, the direction of the $s$ component is almost exactly reversed on reflection, but, since metals have high reflectivities in the infrared, its magnitude is little changed. Electric vectors $E_s$ and $E_p$ are hence almost exactly equal and opposite, and therefore nearly cancel. The behavior of the $p$ component depends somewhat on the angle of incidence, $\theta$, but when $\theta$ approaches 90° (i.e. at glancing incidence), the fields combine to give a large component perpendicular to the surface and a much smaller one parallel to it. The $\theta$-dependence of the resultant fields is shown in Figure 2. Bearing in mind that absorption intensity is proportional to the square of the amplitude of the electric field vector, it will be appreciated that at no angle of incidence is there a significant field parallel to the surface, but that an enhanced field perpendicular to the surface arises from the $p$ component at angles close to grazing.

There are two immediate and important consequences of this. The first is that the sensitivity is maximized by employing high angles of incidence. In this regard, the field enhancement already noted is augmented by a simple geometric factor: at glancing angles the beam covers a larger area of surface and hence more molecules. The combined effect of the two factors in a typical case is shown in Figure 3, where it can be seen that the relative sensitivity is sharply peaked at an angle close to grazing. In practice, it is usually not possible to exploit this enhancement fully, partly because the incident beam subtends a range of angles at the surface and partly because at very high angles the projected width of the beam is often larger than the sample width. Bradshaw and Schweizer have shown how the enhancement depicted in Figure 3 is modified by the adoption of a more realistic experimental geometry, concluding that optimum performance should be achieved at an angle a few degrees closer to the normal than the figure would indicate. Nevertheless, the basic principle still applies and experiments are almost always performed using an angle of incidence that is fairly close to grazing.

Figure 1 Electric vectors of $s$- and $p$-polarized radiation incident on a metal surface at an angle $\theta$ to the normal. Primed and unprimed vectors refer to the reflected and incident beams respectively.

Figure 2 Resultant electric fields relative to the incident field $E_0$ for infrared radiation incident on a metal with optical constants appropriate to copper at 2000 cm$^{-1}$ ($n = 3; k = 30$). $E_{p\parallel}$ and $E_{p\perp}$ are the components parallel and perpendicular to the surface which arise from initially $p$-polarized radiation. (Reproduced with permission of Elsevier Science from Hollins and Pritchard.)
The second consequence of the optical properties of metal surfaces arises from the fact that it is not possible to establish a large oscillating electric field parallel to the surface. Any dipole lying parallel to the surface will hence be subject to only very small variations in the electric field along its length and will therefore scarcely interact with the incident radiation. We can hence establish the MSSR as developed by Pearce and Sheppard. This states that “only those modes which have vibrational dipole moments with components perpendicular to the metal surface will have measurable intensities”. The original discussion of this was couched in terms of image dipole effects which are formally equivalent to the argument already given, but are perhaps easier to grasp intuitively. A famous result in electrostatics states that the field due to a charge situated a distance $d$ above a perfectly conducting plane is identical to that in which the conductor is replaced by a second charge, equal to the first but opposite in sign, placed a distance $d$ below the plane. When this formalism is applied to the two charges that constitute a dipole above a (planar, conducting) metal surface, a clear distinction between parallel and perpendicular dipoles is evident (Figure 4). When the dipole is parallel to the surface, it is opposed by its image. Since the separation between the real and image dipoles is of molecular dimensions and accordingly much smaller than infrared wavelengths, their interactions with infrared radiation cancel essentially perfectly and no absorption can occur. Dipoles perpendicular to the surface, however, reinforce each other, and enhanced absorption is accordingly observed.

The MSSR is often of great help in interpreting RAIRS spectra. For example, at low coverages the spectrum of benzene adsorbed on the silver (100) surface exhibits a single band, whose wavenumber corresponds to that of the out-of-plane deformation mode (Figure 5). This band persists as the coverage is raised to multilayers, but additional bands with wavenumbers corresponding to various in-plane stretches and deformations also appear. The interpretation of these results in terms of the MSSR is that at low coverages the plane of the molecule lies strictly parallel to the surface, so that only the out-of-plane mode is infrared active. At multilayer coverages, the appearance
of extra bands shows that the molecules are no longer all parallel to the surface. This could arise either through tilting of the molecular plane, or by the development of a structure in which some molecules remain parallel to the surface, but others are perpendicular to these: the latter case corresponds to the structure of bulk benzene and is hence the preferred explanation.

Although the MSSR is of great utility, some care must be exercised in its application. One example of this arises in the analysis of spectra from strongly polarizing species such as dioxygen. On a number of substrates oxygen has been found to adsorb molecularly in the peroxide form where the O–O bond is believed to lie strictly parallel to the surface, but where the O–O stretching vibration can nonetheless be observed. The explanation for this is that the metal–oxygen bond is strongly polar and that the charge separation in this depends on the O–O separation. When the O–O stretching vibration is excited, the changes in the O–O bond that occur during the course of the vibration engender concomitant changes in the metal–oxygen bonds, so that an oscillating dipole is established perpendicular to the surface. Since this oscillates at the same frequency as the primary O–O stretching vibration, an absorption band having the same wavenumber as the O–O stretch is observed in the RAIRS spectrum.

It has been shown that modes involving dipole changes which are strictly parallel to a metal surface can sometimes give rise to antiabsorption bands in RAIRS spectra (that is they produce increases in surface reflectivity relative to neighboring regions of the spectrum). This phenomenon, which has chiefly been observed with low-frequency frustrated translations and rotations of the adsorbed species, has been explained in terms of a model that invokes the surface resistivity which the metal conduction electrons experience. Scattering of these electrons by the adsorbate molecules leads to a very broad background absorption in the infrared. However, when the frequency of the incident radiation equals the resonance frequency of a parallel mode, the molecules and the conduction electrons move together, the additional surface resistivity is eliminated, and the background absorption is reduced, leading in turn to the apparent antiabsorption feature. It has been argued that these antiabsorption resonances constitute exceptions to the MSSR, but it is perhaps more useful to envisage them simply as a consequence of an excitation mechanism different from that underlying conventional infrared absorption. Viewed in this context, they are no more exceptions to the MSSR than are the impact excitations of parallel modes observed in vibrational electron energy loss spectroscopy (VEELS) (section 3.4). In any case, since the appearance of these bands is almost precisely opposite to that of an absorption band, confusion between the two is unlikely to arise.

The chief constraint on application of the MSSR, however, is that it is valid only for highly conducting materials, as epitomized by metals. This is true for the whole of the foregoing discussion in this section. Semiconductors and insulating materials lack the high reflectivity of metals in the infrared and accordingly give rise to much weaker absorption bands. RAIRS is therefore a less useful technique for the study of adsorption on such surfaces, which are usually investigated by attenuated total reflectance or by transmission infrared spectroscopy as discussed in a review by Horn. One method of applying RAIRS to such surfaces, however, is to generate (by evaporation or chemical reaction) a thin layer of nonmetal on a metal substrate. Since the wavelength of infrared radiation is long compared with the distances over which chemical interactions take place, it is possible by this means to create a surface whose chemical properties are dominated by those of the overlayer, but which behaves optically as a metal. In the case of silicon overlayers, the real part of the refractive index is close to that of many metals and layers several tens of nanometers in thickness deposited on a metal substrate exhibit optical properties that are essentially metallic in character, as Figure 6 demonstrates. Horn has compared the RAIRS spectrum of a hydrided silicon surface with that of a surface prepared by depositing a silicon layer four atoms thick on a ruthenium substrate and then forming the hydride, finding that the composite substrate yields Si–H stretching bands almost an order of magnitude more intense than the pure silicon, and with a corresponding improvement in S/N ratio.

A similar procedure has been widely used to investigate adsorption on ice surfaces in order to model heterogeneous processes occurring on atmospheric ice particles that are known to be important in stratospheric chemistry. Instead of attempting to carry out RAIRS using a solid ice substrate, a thin (ca. 10 nm) layer of ice is prepared on an inert metal substrate by condensation from the vapor phase. The optical properties of the resulting compound substrate are dependent on wavelength, since ice itself shows strong absorption bands in the mid-infrared, and the design of the RAIRS experiment has to be modified to take this into account.

Returning now to metal surfaces, it might appear that the sensitivity to weakly absorbing species could be enhanced by the use of multiple reflection techniques to sample the adlayer repeatedly. As noted in the previous section, Pickering and Eckstrom employed this method in the earliest RAIRS study, using a multiple reflection White’s optics cell in which the mirrors served as the substrate for adsorption. However, Greenler showed that this seemingly attractive possibility for improving sensitivity is limited by the imperfect reflectivity of the substrate, which results in a loss of energy at each
reflection even in regions of the spectrum where the adsorbate does not absorb. In consequence, although the relative absorption intensity increases at each reflection, the absolute intensity attains a maximum after a rather modest number of reflections. If further reflections are attempted, the magnitude of the signal decreases, and, provided that detector noise is the limiting factor (as it usually is), the S/N ratio deteriorates. The number of reflections required to give the maximum signal is given by the integer closest in value to the expression in Equation (1)

\[
N_{\text{max}} = \frac{\ln \left( \frac{\ln R_0}{\ln R} \right)}{\ln (R/R_0)}
\]  

where \( R \) and \( R_0 \) are the reflectivities at the center of the absorption band and away from this band, respectively. Greenler showed that with most metals a single reflection will produce a large fraction (>60%) of the maximum signal theoretically attainable using multiple reflections. The experimental difficulties which attend the implementation of multiple reflection spectroscopy have accordingly been thought to outweigh the small advantages which the technique could in principle provide, at least for single crystal substrates. However, multiple reflections are sometimes employed in the study of polycrystalline materials.

The discussion so far has concentrated on the substrate and no explicit consideration has yet been given to the influence that the optical properties of the adsorbate have on the RAIRS spectrum. The pioneering paper in this area was that of McIntyre and Aspnes,\(^{14}\) who obtained analytic solutions for the change of reflectance \((\Delta R/R)\) for the situation in which an adlayer of thickness \( d \) and complex refractive index \( n - ik \) overlies a metal substrate. Making approximations valid for submonolayer coverages of an isotropic adsorbate which is fairly weakly absorbing and for an angle of incidence \( \theta \) which is not too high, these expressions yield the result in Equation (2) for the reflectance change for \( p \)-polarized radiation of wavelength \( \lambda \).

\[
\frac{\Delta R}{R} = -\frac{4 \pi kd}{\lambda} \left( \frac{4 \sin \theta \tan \theta}{n^3} \right)
\]  

The first factor in this equation corresponds to the familiar attenuation factor \( e^{-cl} \) in the Beer–Lambert law, while the second corresponds to the field and geometrical enhancements alluded to earlier. This part of the expression takes the same form as that derived from the situation in which the adsorbate is neglected, apart from the inclusion of the factor \( n^3 \) in the denominator. Accordingly, to take proper account of the adsorbate, the absorption intensities in Figure 3 should be reduced by this factor, but the conclusions are otherwise unchanged at this level of approximation.

Subsequent work by a number of authors has extended the calculations of McIntyre and Aspnes. Specific additions to the theory include treatment of the adsorbate as a uniaxial or biaxial medium rather than as an isotropic one, extensions to thicker or multiple films and to more strongly absorbing adlayers, consideration of a wider range of substrate optical parameters to include semiconductors and dielectrics as well as metals, and inclusion of the effects of surface roughness. The essential physics behind these calculations is simply an application of Maxwell’s equations to the case of an infinite plane electromagnetic wave interacting with a layered structure, and is accordingly well understood in principle. However, as might be expected, increasing complexity of the adlayer system leads to significant computational difficulties, especially when thick multilayers of strong absorbers are being considered.

Early methods of calculation concentrated on finding analytic solutions at appropriate levels of approximation, but more recent work has favored the use of numerical simulation. A particularly comprehensive approach along
these lines has been described by Parikh and Allara, who discuss procedures for the quantitative simulation of both reflection and transmission spectra from multilayer anisotropic systems. As part of its input, such a simulation requires optical parameters for each substrate and adlayer material in the form of a frequency-dependent complex refractive index or permittivity, which in the most general form for an anisotropic medium is described by a tensor quantity. One difficulty arising from this is that for many organic materials this tensor may not be known, either because the large single crystals needed to make the appropriate optical measurements are not available, or because these measurements are themselves too demanding. To circumvent this problem, Parikh and Allara also describe a means for estimating the tensor from experimental measurements made on bulk isotropic material, such as a random dispersion of small crystallites in a matrix of potassium bromide or some similar inert material.

These advanced optical methods allow the simulation of spectra from complex layered systems, such as Langmuir-Blodgett and self-assembled films formed from large organic molecules. It should be noted, however, that in practice most experimental results from simpler systems can be dealt with adequately either by using the simplified theory of McIntyre and Aspnes discussed earlier, or even by giving no explicit regard to the optical properties of the adlayer.

In comparing RAIRS measurements with those from other nonsurface infrared spectroscopies, it is often convenient to express the observed intensities in terms of the magnitude of the dynamic dipole involved in the oscillation. The experimental measure of intensity for an absorption band in RAIRS is the integrated absorbance defined by the relationship in Equation (3)

\[ A = \ln \left( \frac{R_1}{R_2} \right) d\tilde{v} \]  

where \( R_1 \) and \( R_2 \) are respectively the surface reflectivities in the absence and presence of the adsorbate, and \( \tilde{v} \) represents wavenumber. In the general case, when the surface film has significant thickness, the relationship between this quantity and the magnitude of the dynamic dipole is complicated. However, for a submonolayer film with the dipoles oriented perpendicular to the surface, it reduces to Equation (4)

\[ A = \frac{1}{4\pi e_0} \frac{4\pi^2 n_s \tilde{v}_p \mu^2 \sin \theta \tan \theta}{c h} \]  

where \( n_s \) is the adlayer density (molecules per unit area), \( \tilde{v}_p \) the wavenumber of the peak absorbance and \( \mu \) the dynamic dipole. After evaluation of the various constants, this yields Equation (5)

\[ \mu = 2.985 \times 10^{-10} \frac{A}{\tilde{v}_p R_2 \sin \theta \tan \theta} \]  

In comparing different oscillators, it is convenient to express the dynamic dipole in terms of the effective charge which moves during the oscillation \( (e^*) \). This is given by Equation (6)

\[ \mu = e^* \frac{\hbar}{4\pi c m_r \tilde{v}_p} \]  

where \( m_r \) is the reduced mass of the oscillator. In terms of the molar reduced mass \( M_r \) and electronic charge \( e \), this can be expressed as Equation (7)

\[ \frac{e^*}{e} = 4.538 \times 10^8 \frac{(A/m^{-1})(M_r/g\text{ mol}^{-1})}{(n_s/m^{-2}) \sin \theta \tan \theta} \]  

For strongly absorbing species, the value of \( e^* \) is a substantial fraction of \( e \).

The above equations assume that the real dipole is enhanced by its image (Figure 4): values of \( \mu \) and \( e^* \) twice those given by the above expressions are appropriate if this assumption is not made.

### 3 EXPERIMENTAL TECHNIQUES

#### 3.1 General Considerations

The requirements for a RAIRS experiment have essentially been defined in the previous section: it is necessary to record the reflectance spectrum of the substrate with a high (S/N) ratio both before and after adsorption, and then to compare the resulting spectra. This final stage is now almost invariably achieved by digital ratioing. As Figure 3 illustrates, the angular range of the incident beam that can be effectively utilized is rather limited. This, combined with the small size of the sample, ensures that the étendue (the conserved product of image size and the solid angle subtended) is much smaller than in most other applications of infrared spectroscopy: values between \( 10^{-1} \) and \( 10^{-2} \text{ mm}^2 \text{sr} \) are typical. This has implications for the design of the experiment, particularly in terms of the types of source and detector that are appropriate.

The sensitivity of RAIRS is obviously dependent on the attainable noise levels. These are typically in the region of a few parts in \( 10^5 \) throughout most of the infrared spectrum, although in the region below about \( 600 \text{ cm}^{-1} \) special sources are needed to achieve this, as will be discussed in section 3.2. This noise level corresponds to
a sensitivity of about $10^{-4}$ monolayers in the case of adsorbates with particularly strong infrared absorption bands (of which carbon monoxide is the archetype). In less favorable cases, such as the rather weakly absorbing C–H stretching vibrations of hydrocarbons, sensitivity is reduced to a value typically in the range $10^{-2}$ to $10^{-1}$ monolayers.

In comparison with many other techniques of surface science, RAIRS possesses the considerable advantage that the probe photon can propagate through nonvacuum environments. This enables the spectrometer to be set up outside the ultra-high vacuum (UHV) chamber, which considerably simplifies operation: not only can materials incompatible with UHV environments be used in construction, but repair and maintenance are facilitated by the absence of any need to break the vacuum in order to perform them. The only modification that is required of the UHV chamber itself is the addition of suitable infrared-transmitting windows. Sapphire or calcium fluoride windows were frequently used during the period when RAIRS was being developed, since they are robust, nonhygroscopic, and available commercially already mounted in UHV-compatible flanges. More recently, alkali halide windows (sodium chloride, potassium bromide, or cesium iodide) have been preferred because of their wider transmission range and, in the first two cases, lower cost. The thermal expansion coefficients of these materials are much higher than that of stainless steel and compensation must be made for this to avoid failure of the window when the UHV system is baked. The usual procedure is to mount the window between O-rings made from a high-temperature elastomer such as Viton, with UHV-compatibility being achieved through differential pumping between these and another O-ring sealing against atmosphere. The alkali halides are also hygroscopic and must be protected against excessive exposure to moist air. Potassium bromide windows permit operation down to 400 cm$^{-1}$, while the cut-off for cesium iodide lies below 200 cm$^{-1}$. Cesium iodide is much softer than potassium bromide, but this may prove advantageous in some circumstances, since mechanical or thermal shock is likely to be accommodated by the material deforming, rather than suffering a potentially much more serious fracture.

For many applications, the ideal infrared window material is diamond, which combines great strength with chemical inertness and excellent thermal properties. To obtain good transmission in the infrared, clear diamonds of low nitrogen content (designated as Type IIA diamond) must be used. Until recently, these have been prohibitively expensive in the sizes required for RAIRS applications, but the increasing availability and rapidly diminishing cost of large synthetic diamonds prepared by chemical vapor deposition (CVD) is changing this situation. Natural Type IIA diamonds and CVD diamonds exhibit essentially identical infrared spectra; both are highly transparent throughout the mid-infrared region (and, indeed, through much of the ultraviolet (UV) and X-ray region), but they do show some absorption around 2000 cm$^{-1}$. However, this absorption is relatively weak and can be minimized by the use of very thin windows which, because of diamond’s great strength, can still support a differential pressure of an atmosphere. The high refractive index of diamond (2.4) necessitates the use of windows mounted at the Brewster angle if excessive losses through reflection are to be avoided.

Although infrared radiation is much more tolerant of gas-phase species than other surface probes such as electrons, it is obviously advantageous to eliminate any such species that exhibit very strong absorption bands. In studies in the mid-infrared region of the spectrum, it is usual to remove water vapor and carbon dioxide from the spectrometer by purging with air that has been passed through appropriate molecular sieve filters to remove these gases. In the far-infrared, water vapor is particularly troublesome and the use of vacuum spectrometers (operating at about $10^{-2}$ mbar) is generally advocated.

Until the mid-1980s, almost all RAIRS experiments were performed using dispersive spectrometers, often extensively modified in order to optimize performance. Various techniques were used to improve these spectrometers, including wavelength modulation, polarization modulation, double-beam spectroscopy, and infrared ellipsometry. These methods have been reviewed in some detail elsewhere. Polarization modulation and infrared ellipsometry both achieved an improvement in performance by utilizing the difference in behavior of s- and p-polarized radiation to obtain an effective double-beam effect, while wavelength modulation produced a signal proportional to the derivative of the conventional spectrum, thereby emphasizing sharp spectral features such as adsorbate absorption bands. More recently, however, these specialized dispersive instruments have been almost entirely displaced by FTIR spectrometers, which are often applied to RAIRS studies with little or no modification of the standard commercial instrument. Nevertheless, there are indications that readoption of now rarely used techniques may prove valuable for some applications, particularly for studies at relatively high gas pressures, where infrared absorption by the phase surrounding the sample is significant. This topic will be considered again in section 3.3.

An extreme case of absorption of infrared radiation by the medium surrounding the surface under study occurs in aqueous solutions, where variants of RAIRS have been widely employed to study adsorption and reaction at
metal electrode surfaces. Two different techniques are usually combined in order to record spectra from surfaces immersed in water, which exhibits very strong infrared absorption bands. First, the path length through the water is minimized by placing the surface very close to the infrared-transmitting window. Separations of the order of micrometers are often used, and prismatic windows are employed in order to achieve the optimum high angle of incidence at the sample. The short path length through the water permits a reasonable proportion of the infrared radiation to be transmitted, but the absorption bands are still strong and would normally swamp any bands due to monolayer quantities of adsorbate, so an additional means of discriminating against liquid-phase absorption is required. This is achieved by varying the potential applied to the electrode in order to disrupt and reform the adlayer. If, as is usually the case, the infrared spectrum of the liquid phase is unchanged by this change in potential, then the difference between spectra recorded at the two potential differences corresponds to the difference between the surface spectra at these potentials. Spectra from electrodes were first recorded at high sensitivity using a method known as EMIRS (electrochemically modulated infrared spectroscopy) which employed a dispersive spectrometer operating at a slow scan rate in conjunction with a relatively rapid (several hertz) modulation of the potential. As FTIR spectrometers began to supplant the dispersive variety, this was largely replaced by SNIFTIRS (subtractively normalized interferential Fourier transform infrared spectroscopy), in which a series of scans are taken to obtain a spectrum at a particular potential, the potential is changed, and a second spectrum then recorded. The rapid modulation used in EMIRS is particularly effective in eliminating the effects of drift, and very high SN ratios are attainable, allowing reflectance changes to be detected at the part per million level. The ultimate sensitivity of SNIFTIRS is somewhat poorer than this, but this disadvantage is usually outweighed by the greater range of potentials that can be employed: while EMIRS is restricted to the study of systems oscillating between two stable configurations, SNIFTIRS can be used to monitor the changes accompanying irreversible voltammetric reactions.

In conventional infrared spectroscopy, FTIR spectrometers exhibit three well-known advantages over scanning dispersive instruments. The first of these, the Fellgett or multiplex advantage, derives from the fact that the spectrometer samples the whole spectral range simultaneously, while a scanning instrument can sample only one resolution element at a time. The measurement time for a spectrum at a given S/N ratio is accordingly reduced by a factor equal to the number of resolution elements, \( N \) (numerically equivalent to the width of the spectral range being scanned divided by the resolution). Alternatively, given a fixed measurement time, the S/N ratio is improved by a factor equal to the square root of \( N \). Since \( N \) is typically of the order of \( 10^3 \), the advantage is generally substantial. In RAIRS, where one seeks to measure a very small change in the signal, the multiplex advantage applies, although it imposes considerable demands on the dynamic range of the spectrometer’s detector and analog-to-digital converter (ADC) which will be discussed further in section 3.3.

The second advantage of FTIR spectroscopy, the Jacquinot or throughput advantage, arises because slits are not required in the spectrometer to define a resolution element. Hence, the throughput, or radiation flux, through an FTIR instrument is higher than through a dispersive one, especially at high resolution. In RAIRS, where the small sample size defines a low étendue, it might be expected that the throughput would always be limited by the sample, even with a dispersive spectrometer, and that the Jacquinot advantage would therefore not apply. However, Bradshaw and Schweizer have demonstrated that while this is likely to be true for measurements in the far-infrared, it is often not so in the mid-infrared. They calculate that when using a standard dispersive instrument incorporating a monochromator of 300 mm focal length, the slits rather than the sample become throughput-limiting when the resolution reaches 4 cm\(^{-1}\), and that the Jacquinot advantage will accordingly apply at higher resolutions. Allied to the Jacquinot advantage is the observation that when using an FTIR spectrometer, the resolution can be improved simply by increasing the distance through which the moving mirror of the interferometer travels, without otherwise changing the optical arrangement. With a dispersive instrument, the equivalent procedure of reducing the slit width is inevitably more complicated and frequently requires subsequent realignment of the optical path in order to optimize the signal.

The third well-known advantage of FTIR spectrometers, the Connes advantage, relates to the internal calibration of the wavenumber scale provided by the spectrometer’s helium–neon laser, and is obviously relevant to RAIRS operation.

As well as these advantages which apply to all areas of infrared spectroscopy, FTIR spectrometers have conferred at least two benefits specifically to RAIRS. The first is the ability to scan an extended wavelength range in a single spectrum. Although the best S/N performance achieved using dispersive spectrometers was probably as good as that subsequently attained by FTIR, it was necessary to optimize the spectrometer for a limited wavenumber range, typically less than 200 cm\(^{-1}\) in width. Operation outside this range required grating and filter changes which were time-consuming and, in practice,
rarely performed. Only after the introduction of FTIR technology to RAIRS did the scanning of a wide spectral range become in any way routine. The second benefit derives from the fact that FTIR instruments sample all spectral elements simultaneously. With dispersive spectrometers, the limiting S/N performance was often imposed not by the short-term performance of the detector and its associated electronics, but by much longer-term drifts in detector sensitivity, source temperature, optical alignment, and similar factors. The techniques applied to improve the performance of dispersive spectrometers, particularly wavelength and polarization modulation, achieved their effect mainly by minimizing the influence of these drifts. With FTIR spectrometers, however, such drifts affect all parts of the spectrum almost equally and special techniques are not required to reduce them.

3.2 Infrared Sources

In the vast majority of RAIRS investigations, conventional thermal sources have been used. Such sources are typified by the globar, a silicon carbide rod which is heated resistively, usually to between 1100 and 1500 K, when it behaves as a near-perfect gray body (i.e. constant emissivity) source. Operated in this way, the globar maintains high intensity levels throughout the mid-infrared region between 1000 and 4000 cm\(^{-1}\). It also has sufficient thermal inertia to ensure that it is not overly sensitive to short-term fluctuations in its cooling, and subject to the obvious condition that its power supply must be adequately stabilised, it generally gives good performance in this spectral region, although higher-temperature sources (e.g. a tungsten ribbon at approximately 3000 K) are sometimes preferred at the high wavenumber end of the range.

As one moves toward lower wavenumbers, however, thermal sources become increasingly inadequate, to the extent that few RAIRS studies have investigated the range below 600 cm\(^{-1}\). The reason for this lies in the form of the blackbody radiation curve, as Figure 7 illustrates. It is clear that while the total output integrated over all wavelengths rises very rapidly with temperature (as \(T^4\), following the Stefan–Boltzmann law), the bulk of this additional power is concentrated in the high wavenumber region and intensity at low wavenumbers never approaches that in the mid-infrared. Indeed, in the longwave Rayleigh–Jeans limit the intensity is proportional only to \(T\). Since the output of a 3000 K source is approximately 30 times greater at 2000 cm\(^{-1}\) than at 300 cm\(^{-1}\), reasonable power at the lower wavenumber could be obtained from a thermal source only at temperatures in the vicinity of 10^5 K which are obviously unattainable in practice. In many applications of infrared spectroscopy, this loss of intensity at longer wavelengths can be offset by increasing the source size (i.e. étendue), but as already noted, the narrow angular spread of the usable beam in RAIRS reduces the available étendue to a low value, typically in the range \(10^{-2} - 10^{-1}\) mm^2 sr. Since increasing the source size is not an effective strategy, a means must be found to increase the absolute brilliance (i.e. power per unit étendue) of the source.

Several groups have now attained this brilliance by the use of synchrotron radiation from a storage ring. Although synchrotron radiation is normally considered as a source of short wavelength radiation (X-rays and vacuum UV), it does contain a significant component in the far-infrared. For example, the synchrotron radiation source at the Daresbury Laboratory, England, operating

![Figure 7](image-url)

**Figure 7** Intensity per unit wavenumber interval for a blackbody source at the temperatures indicated. (a) In the mid-infrared, (b) in the far-infrared.
with an electron current of 300 mA at 2 GeV, has an output in the far-infrared equivalent to that of a blackbody source at a temperature in excess of 650 000 K, about 450 times that of a globar. However, the effective size of the source varies with wavelength, and in the near-infrared the available étendue is small even by the standards of RAIRS, so that thermal sources can actually deliver more power. As one moves toward longer wavelengths, the source étendue increases, and the storage ring starts to deliver more power than a thermal source. Table 1 shows the relative performance of the Daresbury source against a 1500 K blackbody as a function of wavenumber for a range of experimental étendues. Recalling that the relevant range for RAIRS is approximately $10^{-2}$ to $10^{-4}$ mm$^2$ sr, it is seen that the advantage over the thermal source first becomes evident at about 1000 cm$^{-1}$, that this advantage has increased to approximately one order of magnitude at 330 cm$^{-1}$, and reaches a limiting value close to 450 at the longest wavelengths, in accordance with the effective blackbody temperature of the synchrotron source.

Infrared beamlines for RAIRS applications are now in operation at several storage rings, with many others under construction. The possibility of extending the technique to longer wavelengths has a number of potential applications, but the one that has been exploited most to date is that of studying the vibrations of the primary chemisorptive bond between substrate and adsorbate. Except in the special case of the lightest atom, chemisorbed hydrogen, these vibrational features usually lie below 700 cm$^{-1}$ and are hence difficult to observe using conventional sources. They are of course especially important in the case of atomic adsorbates, where the atom–substrate bond is necessarily the only one. The chemistry of atomic adsorbates is of major significance in catalysis, since heavy adatoms in the third and subsequent rows of the periodic table – such as sulfur, chlorine, and potassium – are widely recognized to act as poisons or promoters in a great variety of catalytic reactions. Figure 8 shows the first recorded infrared spectrum of such a heavy atomic adsorbate, chlorine on the silver (100) surface, recorded using synchrotron radiation. Other potential topics of interest in the far-infrared include the stretching modes of molecules containing heavy atoms (such as halides and the organometallics employed in semiconductor device fabrication and CVD processes), surface phonons (and their coupling with adsorbed species), and deformation modes, including frustrated rotations and translations.

Certain technical problems attend the use of synchrotron sources for RAIRS, especially in high-energy storage rings, where the electrons have kinetic energies in excess of 1 GeV. Since such kinetic energies are equivalent to several thousand times the rest mass of the electron, major relativistic effects arise. One consequence of these is that length contraction in the direction of motion results in a strongly directional beam throughout most of the electromagnetic spectrum: beam divergence in the X-ray region is less than one milliradian. In the infrared region, however, the source size is comparable with the wavelength, so that diffractive spreading increases the beam divergence to several tens of milliradians. In order to capture this beam using optical components of reasonable size, a mirror must be placed close to the tangent point where the electrons emit the synchrotron radiation: in the Daresbury beamline this mirror is 1.08 m from the tangent point. However, at this distance very little spreading of the

*Entries in bold are typical for a RAIRS experiment.*
shorter wavelength X-ray and UV radiation has occurred, so the central region of the mirror is exposed to a very high flux of these components, leading to massive thermal loads. At Daresbury, these are overcome partly by integral water cooling of the mirror and partly by inserting a cooled stop of copper piping into the beam path immediately before the mirror (Figure 9). (Other solutions are possible and a particularly attractive one which is being explored is the possibility of cutting a central hole in the mirror through which the short-wavelength radiation passes to be utilized elsewhere: hence a single beamline could serve as a combined X-ray/infrared source.) After deflection by this primary mirror, the beam is focused by an ellipsoidal mirror onto a Brewster-angle diamond window which separates the UHV of the storage ring from the RAIRS system.

As well as high intensity in the far-infrared, synchrotron sources possess other potential advantages. The radiation is strongly polarized in the plane of the ring and so can be delivered to the sample as almost pure p-polarized radiation. The electrons are also distributed around the ring in evenly spaced “bunches” with gaps between them. This results in the emitted radiation having a temporal structure on the nanosecond scale that has potential applications for time-resolved studies, although this has yet to be exploited.

High intensity, polarization, and temporal structure are, of course, major advantages of lasers, which also emit a highly collimated beam that would allow the sharply peaked intensity curve of Figure 3 to be exploited to the full. It is perhaps surprising, therefore, that lasers have not been more widely employed in RAIRS. Attempts to use them have in fact been made by several groups, but the results have generally been inferior to those obtained with thermal sources and have been achieved only with a marked increase in the complexity of the experiment. Although lasers can now offer adequate tunability throughout the infrared region, together with much higher powers than either thermal or synchrotron sources, attaining sufficient stability for RAIRS studies appears to pose major difficulties. However, the potential advantages of lasers are so great that it seems very likely that in the long term these difficulties will be overcome.

3.3 Spectrometer Design

As already noted, most RAIRS work is now carried out using standard commercial FTIR spectrometers with minimal modifications made to accommodate the reflection experiment, which is most commonly carried out with the sample housed in a (relatively large) UHV chamber equipped with facilities for a range of other surface science techniques. Typical chamber and infrared window dimensions constrain the experimental optics to an aperture of f/5 or less, corresponding to an acceptance angle of no more than 12°, but this angle is sufficient to encompass the peak in the surface intensity function (Figure 3). Consideration must also be given to the optical arrangement used to extract the infrared beam from the spectrometer, focus it into the UHV chamber, reflect it from the surface under study, and then refocus it onto the detector. The most usual configuration, shown in Figure 10(a), involves deflecting the beam, after passage through the interferometer, out of the external port with which most commercial FTIR spectrometers are fitted. A (usually parallel) beam of radiation exits the spectrometer from this port and is focused onto the sample using either an alkali halide lens or an arrangement of mirrors. (Use of a lens affords a cheap solution which also allows a particularly simple optical path to be employed, but it suffers from chromatic aberration together with transmission and reflection losses.) After reflection from the surface, the beam is refocused onto an external detector whose signal is fed back into the processing circuitry of the spectrometer. One disadvantage of this configuration is that visual alignment of the optical path external to the spectrometer may be difficult, since the beam splitters used in mid-infrared FTIR instruments often have relatively poor transmission of visible light, while far-infrared beam splitters are frequently totally
of the detection optics is large and more radiation is accepted from the beam splitter than is necessary. Reduction of the detector acceptance angle to optimize it for RAIRS experiments would virtually eliminate the problem of beam splitter emission, but this has rarely been attempted.

Chesters(7) and Bradshaw and Schweizer(9) have discussed the constraints placed on a RAIRS spectrometer by the requirement for a high dynamic range. RAIRS differs from many applications of infrared spectroscopy in that it involves detection of a very small change in signal level: the reflectance change following adsorption is usually less than 1% and in some applications may be less than 0.01%. With dispersive instruments, each spectral element is collected separately, so that detection of a 0.01% band requires an S/N ratio of $10^4$. With FTIR instruments, a large number, $N$, of spectral elements are monitored simultaneously and the change in signal is spread over all of these elements. In the absence of the multiplex advantage, this would require an increase in S/N by a factor of $N$ to attain the same sensitivity, but since the whole interferogram contributes to the signal at any point, this factor is reduced to the square root of $N$. Even so, the required S/N is much higher than with a dispersive instrument: scanning a range of 3200 cm$^{-1}$ at a resolution of 2 cm$^{-1}$ generates 1600 spectral elements, so the S/N ratio has to be improved by a factor of 40, to $4 \times 10^5$ in the case just discussed.

Such high ratios are achieved by co-adding a large number of individual scans, each with a much poorer S/N value. The FTIR spectrometers used are accordingly rapid-scan instruments with which a single interferogram can be recorded in a fraction of a second. Attention must also be paid to the resolution of the spectrometer’s ADC. In the earliest applications of FTIR to RAIRS, 15- or 16-bit ADCs were typically used. Since in normal operation of an FTIR instrument the last two bits (at least) of the ADC contain only noise, the attainable S/N in a single scan from such an instrument is limited by the performance of the ADC alone to a value of about $(2^{13}/\sqrt{1600}) \approx 200$. Improvement of this to the desired value of $10^5$ would then require the co-addition of approximately $(10^5/200)^2 = 2500$ scans. This number may be reduced by using ADCs of 20-bit or higher resolution which are found in more modern research instruments.

The infrared detector, too, must be able to support this high dynamic range. Most RAIRS investigations in the mid-infrared range currently use liquid nitrogen cooled mercury cadmium telluride (MCT) detectors, which have high saturation levels so that their dynamic range does not often prove limiting. MCT detectors give good performance over a wide wavenumber range, their performance at long wavelengths having improved dramatically in recent years, but for studies in the far-infrared (including especially the synchrotron work described in the previous

![Figure 10](image-url) Alternative optical arrangements for performing RAIRS. (a) Source-interferometer-sample-detector. Source; I, Michelson interferometer; L, alkali halide lens (or equivalent mirror assembly); W, window to UHV chamber; X, single-crystal sample; D, infrared detector.

opaque in the visible. A common solution is to align the beam visually using a near-infrared quartz beam splitter, which transmits well in the visible, and then to replace this with the appropriate mid- or far-infrared beam splitter for spectroscopic measurement. Alternatively, a sensor card which emits visible light when struck by infrared radiation can be used, but the UHV environment near the sample usually ensures that the sensor card cannot be used in just that section of the optical path where alignment is most critical.

An alternative arrangement that avoids this difficulty is to place the source immediately before the sample and to focus the beam reflected from the sample directly into the interferometer/detector section of the spectrometer, as illustrated in Figure 10(b). The beam at the sample position is then much brighter visually. The chief disadvantage of this design compared with that in Figure 10(a) is that the (cooled) detector receives more thermal infrared emission from the (room temperature) beam splitter. Particularly when working in the far-infrared, the magnitude of this spurious beam splitter emission may be comparable with the true signal and a degradation in performance results. The problem is greatly exacerbated by the fact that commercial FTIR spectrometers are designed for high optical throughput, with an experimental étendue at least an order of magnitude greater than that of a typical RAIRS experiment. Hence, the acceptance angle of the detection optics is large and more radiation is
One way of achieving this is to monitor the absorption of gas-phase species toward infrared absorption, of course, makes this a particular advantage of the technique. One such study was a comparatively primitive dispersive one which only allowed the different polarization components to be measured sequentially, rather than simultaneously, but several groups are working on more sophisticated designs. The techniques of polarization modulation and infrared ellipsometry, which were employed to improve the performance of early dispersive spectrometers but fell into disuse after the widespread adoption of FTIR technology, can measure spectra from s- and p-polarized radiation simultaneously. There is a strong likelihood that attempts to model catalytic systems at high pressure will lead to the design of FTIR instruments modified to allow some form of polarization-dependent spectroscopy. Whatever technique is adopted, the potential applications of such studies are so diverse and important that they are sure to play a major part in the future development of RAIRS.

Data acquisition times for modern FTIR spectrometers are sufficiently short to allow measurement of the kinetics of some surface processes. This was exploited by Reutt-Robey et al. in an extremely elegant molecular beam experiment which monitored the diffusion of carbon monoxide molecules on stepped platinum surfaces. The spectrometer was configured to scan and store individual interferograms rapidly (at up to 46.5 Hz, limited by the mechanical turn-round time of the moving mirror). Just before the start of one of these scans, the spectrometer initiated, via an RS-232 interface, a rapid (600 µs) pulse of carbon monoxide from the solenoid-actuated supersonic molecular beam doser. This pulse was adsorbed by the stepped platinum crystal surface to give a low surface coverage (~1% of a monolayer) which was initially randomly distributed between the available adsorption sites, but which diffused over time to occupy the thermodynamically favored step sites. Since molecules adsorbed on the different types of adsorption site exhibit different C=O stretching frequencies, the infrared spectrum can be used to monitor this diffusion process. By recording the proportions of the two species over timescales from a few milliseconds to an hour, and repeating these measurements over a range of substrate temperatures, the activation energy and pre-exponential factor for the surface diffusion process were determined.
The most radical redesign of a UHV system and FTIR spectrometer for RAIRS applications must surely be that described by Brown et al.\(^\text{26}\) Although primarily designed for measurements of infrared emission and chemiluminescence, this system also served, after the addition of potassium bromide windows, for more conventional RAIRS studies. The design was predicated on the need to reduce spurious thermal signals (alluded to earlier in this section in the context of beam splitter emission) to negligibly low values. To this end, the entire optical path between sample and detector (Figure 11) is shrouded in a light-tight enclosure cooled by liquid helium. The optics of the FTIR spectrometer are also cooled to liquid helium temperatures, and since operation of a laser within the cryogenic enclosure would lead to unacceptable heat dissipation, the position of the moving mirror is sensed capacitively. The detector for the most sensitive experiments planned is a cadmium-doped germanium bolometer operating at a temperature of 0.3 K and exhibiting noise levels two orders of magnitude lower than those of a typical MCT detector. However, the saturation level of such an ultrasensitive detector is very low, so a more conventional bolometer, with a working temperature of 4 K, is used to measure higher infrared fluxes.

### 3.4 Comparison with other Surface Spectroscopic Techniques

A range of other techniques are capable of providing vibrational spectroscopic information from the same types of surfaces as RAIRS. The relative advantages and disadvantages of the most important of these are discussed below.

Perhaps the most directly comparable technique is VEELS\(^\text{27}\), which, like RAIRS, has been widely used for fundamental studies of single crystal surfaces. Energy loss spectra are recorded by reflecting a beam of monoenergetic electrons from a surface and then analyzing their energies. Most electrons are scattered elastically, but some (typically, a few per thousand) lose energy to vibrational transitions in the adlayer; a plot of the number of electrons scattered versus their energy loss constitutes the VEELS spectrum, which contains essentially the same information as an infrared spectrum. VEELS rose to prominence in the late 1970s, largely as a result of developments made by Ibach, and at that time it was the only technique capable of recording the entire vibrational spectrum of an adlayer in a single scan. The use of FTIR instruments has since then allowed RAIRS to achieve this also, so the relative merits of the two techniques now lie in other areas.

The relative sensitivities of VEELS and RAIRS are very similar (assuming equal measurement times) in the mid-infrared region, but VEELS has a definite advantage in the far-infrared. This stems not only from the poor intensity of thermal infrared sources in this region (section 3.2), but also from the fact that the performance of most VEELS spectrometers improves at low loss energies. The angular spread of the scattered electrons is smaller at these energies, so the analyzer accepts a

---

**Figure 11** Liquid-helium cooled spectrometer designed for RAIRS and infrared emission measurements. (Reproduced with permission of Elsevier Science from Brown et al.\(^\text{26}\))
larger number of them, provided that this angular spread remains greater than the acceptance angle, as is usually the case. This effect causes the collection efficiency to scale as $v^{-2}$, where $v$ is the wavenumber of the loss peak.

For many years, VEELS could only achieve a much poorer spectroscopic resolution than RAIRS, being limited to several tens of reciprocal centimeters. However, Ibach then showed that reduction of space–charge effects in the spectrometer could improve this markedly\(^{28}\) and spectrometers capable of achieving resolutions of a few reciprocal centimeters are now available commercially. On this basis, RAIRS still maintains a slight advantage, but not nearly to the same extent as formerly. Achievement of high resolution in VEELS, however, is critically dependent on having a well-ordered surface. If the surface becomes poorly ordered (which can happen even with a single-crystal substrate if the adsorbate does not form a well-order overlayer), then scattering becomes more diffuse and it may be necessary to degrade the resolution markedly in order to obtain an acceptable intensity.

The energy-loss process central to VEELS can occur via several mechanisms. The most important of these, dipolar scattering, is formally equivalent to the absorption of an infrared photon, and so obeys the same selection rules, including specifically the MSSR. Other significant mechanisms include impact scattering, which is a shorter-range process than dipole scattering, and negative-ion resonance excitation, which involves the capture of the incident electron by a surface or adsorbate atom, followed by the decay of the negative ion formed in this process. Impact scattering and negative ion resonance are bound by different selection rules from those applicable to dipolar scattering, and the angular distribution of the scattered electrons is also different. VEELS can therefore detect vibrational modes that are inactive in RAIRS and, moreover, it is possible by varying the experimental geometry to establish which of these modes are dipole-allowed and which are not. In some circumstances this additional information can be of considerable use in interpreting the spectrum.

One final area of comparison, where RAIRS certainly maintains an advantage, is in the pressure range over which the techniques can be applied. VEELS, relying as it does on the electrons having sufficiently long mean free paths to travel between the spectrometer and the sample, cannot be employed at pressures much above $10^{-4}$ mbar (even when the surrounding gas is infrared-inactive), whereas RAIRS has been used at pressures more than nine orders of magnitude higher.

Among photon-based spectroscopies, the most obvious alternative to infrared is probably Raman spectroscopy. Since Raman scattering cross-sections are typically very much smaller than infrared absorption cross-sections, the technique would seem to have a clear disadvantage in sensitivity, but submonolayer sensitivity was achieved using then state-of-the-art technology in the mid-1980s.\(^{29}\) Prior to that, the observation of surface enhanced Raman scattering (SERS) caused great excitement when it was found that adsorbates on certain surfaces exhibited Raman scattering cross-sections which were typically four to six orders of magnitude greater than expected from the gas-phase cross-sections. Although it has now been established that SERS effects of this magnitude occur only on a limited range of substrates (mainly roughened surfaces of the coinage metals) and there is still some doubt as to whether the molecules enhanced by SERS are representative of the adlayer as a whole, research in the area remains active. In studies of electrode surfaces, where the beam has to be transmitted through aqueous solution, the low Raman scattering cross-section of water offers a potentially large advantage over RAIRS.

Infrared emission spectroscopy, in which the thermal radiation emitted by the adsorbate is measured directly, was used in the mid-1980s by Richards’s group at Berkeley to obtain an infrared spectrum of the metal–CO stretching vibration from an extended substrate, before RAIRS had attained sufficient sensitivity to observe such vibrations in the far-infrared.\(^{30}\) The apparatus used in these studies was remarkably simple, consisting of a dispersive spectrometer recording the spectra in direct current (i.e. unmodulated) mode. As with the Cambridge instrument described earlier,\(^{26}\) the optics were maintained at liquid helium temperatures and the region between the (room temperature) sample and the spectrometer was screened with cold baffles. Since the blackbody radiation curve for samples at moderate (close to room) temperature peaks at a few hundred reciprocal centimeters, emission spectroscopy is most sensitive to vibrations in this range. As already noted, attempts are currently in progress to develop the technique using more modern instrumentation.

Another vibrational technique that is experiencing rapid development is sum frequency generation (SFG), in which the surface is simultaneously illuminated with a tunable infrared laser and a fixed frequency visible laser.\(^{31}\) When the frequency of the infrared laser matches that of an appropriate vibration of the adsorbate, coherent anti-Stokes Raman scattering leads to resonant scattering at a frequency equal to the sum of the two laser frequencies. Although experimentally complicated, SFG has two substantial advantages as a surface probe. First, by using a pulsed laser, it offers the prospect of time-resolved measurements on a much more rapid scale than can be achieved by RAIRS. Second, the SFG process does not occur in a centrosymmetric medium, so the technique is inherently specific to the interface between two such media. It therefore offers particular scope for
the investigation of interfaces surrounded by liquids or high pressure gases and, as with Raman spectroscopy, has a potentially large advantage over RAIRS for studies of surfaces in aqueous solution.

ACKNOWLEDGMENTS

I am grateful to Dr David Slater and Dr Philip Welch for recording the spectra shown in Figure 5, and to Dr Andrew Horn for providing me with the program used to generate Figure 6.

REFERENCES

The vibrational spectrum of a molecule is considered to be a unique physical property and is characteristic of the molecule. As such, the infrared spectrum can be used as a fingerprint for identification by the comparison of the spectrum from an “unknown” with previously recorded reference spectra. This is the basis of computer-based spectral searching. In the absence of a suitable reference database, it is possible to effect a basic interpretation of the spectrum from first principles, leading to characterization, and possibly even identification of an unknown sample. This first principles approach is based on the fact that structural features of the molecule, whether they are the backbone of the molecule or the functional groups attached to the molecule, produce characteristic and reproducible absorptions in the spectrum. This information can indicate whether there is backbone to the structure and, if so, whether the backbone consists of linear or branched chains. Next it is possible to determine if there is unsaturation and/or aromatic rings in the structure. Finally, it is possible to deduce whether specific functional groups are present. If detected, one is also able to determine local orientation of the group and its local environment and/or location in the structure. The origins of the sample, its prehistory, and the manner in which the sample is handled all have impact on the final result. Basic rules of interpretation exist and, if followed, a simple, first-pass interpretation leading to material characterization is possible. This article addresses these issues in a simple, logical fashion. Practical examples are included to help guide the reader through the basic concepts of infrared spectral interpretation.

1 INTRODUCTION

The qualitative aspects of infrared spectroscopy are one of the most powerful attributes of this diverse and versatile analytical technique. Over the years, much has been published in terms of the fundamental absorption frequencies (also known as group frequencies) which are the key to unlocking the structure–spectral relationships of the associated molecular vibrations. Applying this knowledge at the practical routine level tends to be a mixture of art and science. While many purists will argue against this statement, this author believes that it is not possible to teach a person to become proficient as an interpretive spectroscopist by merely presenting the known relationships between structure and the observed spectra. Instead, the practical approach, which has been adopted in this text, is to help the reader appreciate the visual aspects of the spectroscopy and how to interpret these relative to the structure and chemistry of the sample. This is achieved by recognizing characteristic shapes and patterns within the spectrum, and by applying the information obtained from published group frequency data, along with other chemical and physical data from the sample.

Included in the text is a discussion of the interrelationships that exist between the practical side of acquiring the spectrum, the chemistry and physics of the sample under study, the physical interactions of the sample with its environment, and the impact of the structure on the spectrum. In essence, the interpretation of infrared spectra is much more than simply assigning group frequencies. The spectrum is rich in information, and this article is intended to help the reader extract the maximum using the knowledge available for the sample and the acquired spectral data. One important factor to bear in
mind is that a successful interpretation is based not only on the presence of particular bands within the spectrum, but also the absence of other important bands. Complete classes of compounds can be rapidly excluded during the interpretation by the use of no-band information.

It must be understood that this article addresses the issue of infrared spectral interpretation from the perspective of the average operator of an infrared instrument. It is not a detailed treatise on the theory of infrared spectroscopy where the modes of vibration are discussed in terms of group theory, and where mathematical models are used to compare theoretical and observed values for the fundamental vibrations of a molecule. There are many excellent texts that cover this subject.\(^1-4\) Instead, this article focuses on the day-to-day problems associated with characterizing a material or attempting to perform some form of identification. One of the main challenges in presenting a text on spectral interpretation is to form a balance between the theory that is needed to appreciate the links between molecular structure and the observed spectrum and the practice. For this reason, a minimum amount of relevant theory is included in the next section, which provides a basic understanding of why the spectrum exists, how it is formed, and what factors contribute to the complexity of observed spectra. It has been assumed that the reader has a fundamental knowledge of molecular theory and bonding, and that there is an understanding of basic structures, in particular for organic compounds.

Infrared spectral interpretation may be applied to both organic and inorganic compounds, and there are many specialized texts dealing with these compounds, in combination and as individual specialized texts. There are too many to reference comprehensively, and the reader is directed to a publication that provides a bibliography of the most important reference texts.\(^5\) However, the most informative general reference texts are included,\(^6-14\) with books by Socrates\(^10\) and Lin-Vien\(^11\) being recommended for general organics, and by Nakamoto\(^13\) and Nyquist et al.\(^14\) for inorganics (salts and coordination compounds). There are numerous specialized texts dealing with specific classes of materials, and undoubtedly polymers and plastics form the largest individual class.\(^15-17\) In this particular case, texts by Hummel and Scholl\(^16\) and Koenig\(^17\) provide a good basic understanding.

The following comments are made relative to the conventions used within this article. The term frequency is used for band/peak position throughout, and this is expressed in the commonly used units of wavenumber (cm\(^{-1}\)). The average modern infrared instrument records spectra from an upper limit of around 4000 cm\(^{-1}\) (by convention) down to 400 cm\(^{-1}\) as defined by the optics of the instrument (commonly based on potassium bromide, KBr). For this reason, when a spectral region is quoted in the text, the higher value will be quoted first, consistent with the normal left-to-right (high to low cm\(^{-1}\)) representation of spectra. Also, the terms infrared band, peak and absorption will be used interchangeably within the text to refer to a characteristic spectral feature.

The spectral group frequencies provided in this text were obtained from various literature sources published over the past 30 years, and most of these are included in the cited literature. Every attempt to ensure accuracy has been taken; however, there will be instances when individual functional groups may fall outside the quoted ranges. This is to be expected for several reasons: the influences of other functional groups within a molecule, the impact of preferred spatial orientations, and environmental effects (chemical and physical interactions) on the molecule.

The preferred format for presenting spectral data for qualitative analysis is in the percentage transmittance format, which has a logarithmic relationship (\(–\log_{10}\)) with respect to the linear concentration format (absorbance). This format, which is the natural output of most instruments (after background ratio), provides the best dynamic range for both weak and intense bands. In this case, the peak maximum is actually represented as a minimum, and is the point of lowest transmittance for a particular band.

2 THE ORIGINS OF THE INFRARED SPECTRUM

In the most basic terms, the infrared spectrum is formed as a consequence of the absorption of electromagnetic radiation at frequencies that correlate to the vibration of specific sets of chemical bonds from within a molecule. First, it is important to reflect on the distribution of energy possessed by a molecule at any given moment, defined as the sum of the contributing energy terms (Equation 1):

\[
E_{\text{total}} = E_{\text{electronic}} + E_{\text{vibrational}} + E_{\text{rotational}} + E_{\text{translational}}
\]

(1)

The translational energy relates to the displacement of molecules in space as a function of the normal thermal motions of matter. Rotational energy, which gives rise to its own form of spectroscopy, is observed as the tumbling motion of a molecule, which is the result of the absorption of energy within the microwave region. The vibrational energy component is a higher energy term and corresponds to the absorption of energy by a molecule as the component atoms vibrate about the mean center of their chemical bonds. The electronic component is linked to the energy transitions of electrons as they
are distributed throughout the molecule, either localized within specific bonds, or delocalized over structures, such as an aromatic ring. In order to observe such electronic transitions, it is necessary to apply energy in the form of visible and ultraviolet radiation (Equation 2):

\[ E = \hbar \nu \]  

The fundamental requirement for infrared activity, leading to absorption of infrared radiation, is that there must be a net change in dipole moment during the vibration for the molecule or the functional group under study. Another important form of vibrational spectroscopy is Raman spectroscopy, which is complementary to infrared spectroscopy. The selection rules for Raman spectroscopy are different to those for infrared spectroscopy, and in this case a net change in bond polarizability must be observed for a transition to be Raman active. The remaining theoretical discussion in this article will be limited to a very simple model for the infrared spectrum. The reader is encouraged to refer to more complete texts\(^{(2-4)}\) for detailed discussion of the fundamentals.

While it was stated that the fundamental infrared absorption frequencies are not the only component to be evaluated in a spectral interpretation, they are the essence and foundation of the art. For the most part, the basic model of the simple harmonic oscillator and its modification to account for anharmonicity suffice to explain the origin of many of the characteristic frequencies that can be assigned to particular combinations of atoms within a molecule. From a simple statement of Hooke’s law we can express the fundamental vibrational frequency of a molecular ensemble according to Equation (3):

\[ \nu = \frac{1}{2\pi c} \sqrt{\frac{k}{\mu}} \]  

where \( \nu \) = fundamental vibration frequency, \( k \) = force constant, and \( \mu \) = reduced mass. The reduced mass, \( \mu = m_1m_2/(m_1 + m_2) \), where \( m_1 \) and \( m_2 \) are the component masses for the chemical bond under consideration.

This simple equation provides a link between the strength (or springiness) of the covalent bond between two atoms (or molecular fragments), the mass of the interacting atoms (molecular fragments) and the frequency of vibration. Although simple in concept, there is a reasonably good fit between the bond stretching vibrations predicted and the values observed for the fundamentals.

This simple model does not account for repulsion and attraction of the electron cloud at the extremes of the vibration, and does not accommodate the concept of bond dissociation at high levels of absorbed energy. A model incorporating anharmonicity terms is commonly used to interpret the deviations from ideality and the overall energy–spatial relationship during the vibration of a bond between two atomic centers. The fundamental, which involves an energy transition between the ground state and the first vibrational quantum level, is essentially unaffected by the anharmonicity terms. However, transitions that extend beyond the first quantum level (to the second, third, fourth, etc.), which give rise to weaker absorptions, known as overtones, are influenced by anharmonicity, which must be taken into account when assessing the frequency of these higher frequency vibrations.

Having defined the basis for the simple vibration of an atomic bond, it is necessary to look at the molecule as a whole. It is very easy to imagine that there is an infinite number of vibrations, which in reality would lead to a totally disorganized model for interpretation. Instead, we describe the model in terms of a minimum set of fundamental vibrations, based on a threefold set of coordinate axes, which are known as the normal modes of vibration. All the possible variants of the vibrational motions of the molecule can be reduced to this minimum set by projection on to the threefold axes. It can be shown that the number of normal modes of vibration for a given molecule can be determined from Equations (4) and (5):

\[
\text{number of normal modes} = 3N - 6 \quad (\text{nonlinear}) \quad (4) \\
\text{number of normal modes} = 3N - 5 \quad (\text{linear}) \quad (5)
\]

where \( N \) is the number of component atoms in the molecule.

In practice, apart from the simplest of compounds, most molecules have nonlinear structures, except where a specific functional group or groups generate a predominant linear arrangement to the component atoms. If we calculate the number of modes for a simple hydrocarbon, such as methane (nonlinear, tetrahedral structure), a value of nine is obtained. This would imply that nine sets of absorption frequencies would be observed in the spectrum of methane gas. In reality, the number observed is far less, corresponding to the asymmetric and symmetric stretching and bending of the C–H bonds about the central carbon atom. The reason for the smaller than expected number is that several of the vibrations are redundant or degenerate, that is, the same amount of energy is required for these vibrations. Note that although a small number of vibrational modes is predicted, and in fact observed, the appearance of the methane spectrum at first glance is far more complex than expected, especially at higher spectral resolutions (<1 cm\(^{-1}\)). At relatively high resolutions, a fine structure is superimposed, originating from rotational bands, which involve significantly lower energy transitions. Each of the sets of vibrational–rotational absorptions manifest this superimposed fine structure for low-molecular-weight gaseous compounds, methane being a good example. Several medium-molecular-weight
compounds may also show evidence of some fine structure when studied in the vapor state. For example, it is common to observe the sharp feature (or spike) assigned to the Q-branch of the vibrational–rotational spectrum, as indicated by the vapor spectrum of acetone (Figure 1).

If we proceed up the homologous series from methane (CH₄) to n-hexane (C₆H₁₄), there are 20 component atoms, which would imply 54 normal modes. In this case the picture is slightly more complex. Methane is a unique molecule, and only contains one type of C–H group – no other types of bond exist in this molecule. In hexane there are several types of bond and functionality. For reference, a simple two-dimensional representation of the structure is provided in Figure 2(a).

As we can see, there are two terminal methyl groups (CH₃) and four connecting methylene groups (CH₂). Each of these groups has its corresponding C–H stretching and bending vibrations (see later text for the actual absorption frequencies). Also, the methyl groups are linked to a neighboring methylene group, which is in turn linked to neighboring methylene groups, and so on. These linkages feature carbon–carbon bonds. For interpretation, we view the C–H groups as functional groups, giving rise to the common group frequencies, and the C–C linkages as the backbone, producing the skeletal vibrations. As a rule, a group frequency may be applied generally to most compounds featuring the corresponding functional group. In contrast, the skeletal vibrations are unique to a specific molecule. The group frequencies help to characterize a compound, and the combination of the bands associated with these group frequencies and the skeletal frequencies are used to identify a specific compound. The latter forms the basis of the use of reference spectra for spectral matching by visual comparison or by computer-based searching, for the identification of an unknown from its infrared spectrum.

The group frequencies may be viewed quantitatively, as well as qualitatively. A given absorption band assigned to a functional group increases proportionately with the number times that functional group occurs within the molecule. For example, in the spectrum of n-hexane, the intensities measured for the group frequency absorptions assigned to methyl and methylene correspond to four methylene groups and two methyl groups on a relative basis, when compared with other hydrocarbon compounds within a homologous series. For example, if we examine the C–H stretching (or bending) band intensities for CH₃ and CH₂, we will observe that the relative intensities of CH₃ to CH₂ decrease with increase in chain length. Restated, there is less methyl contribution and more methylene contribution with increase in chain length/molecular weight. The reverse holds true if we examine the spectra of linear hydrocarbons with chain lengths shorter than that of hexane.

If we apply these ideas to a different hexane isomer, such as isohexane (2-methylpentane), we would see significant differences in the spectrum. These can be explained by evaluating the structure (Figure 2b), which contains three methyl groups, two methylene groups, and a group that contains a single hydrogen attached to carbon (the methyne group). This adds a new complexity to the spectrum: the main absorptions show differences in appearance, caused by the changes in relative band intensities, splittings of absorptions occur (originating from spatial/mechanical interaction of adjacent methyl groups), and changes are observed in the distributions of the C–C skeletal vibrations, in part due to the splitting by the methyl side chain. Further discussions concerning the impact of chain branching are covered later in this article.

Comparison of Figures 3 and 4 provides a graphical representation of the aspects discussed for the hexanes of structurally similar compounds, i.e. n-heptane and isooctane.

From a first-order perspective, the idea of the quantitative aspects of the group frequencies carries through for most functional groups, and the overall spectrum is essentially a composite of the group frequencies, with band intensities in part related to the contribution of each functional group in the molecule. This assumes that the functional group does give rise to infrared absorption frequencies (most do), and it is understood that each group has its own unique contribution based on its extinction coefficient (or infrared absorption cross-section).

Returning to the fundamental model, we should now look at the larger picture. In reality, we assign the
observed absorption frequencies in the infrared spectrum to much more that just simple harmonic (or anharmonic) stretching vibrations. In practice, we find that various other deformation motions (angular changes), such as bending and twisting about certain centers within a molecule, also have impact, and contribute to the overall absorption spectrum. By rationalizing the effort needed to move the atoms relative to each other, one can appreciate that it takes less energy to bend a bond than to stretch it. Consequently, we can readily accept the notion that the stretching absorptions of a vibrating chemical bond occur at higher frequencies (wavenumbers) than the corresponding bending or bond deformation vibrations, with the understanding, of course, that energy and frequency are proportionally related. A good example is the C–H set of vibrations, observed in the hydrocarbon spectra, and in virtually all organic compounds. Here, the simple C–H stretching vibrations for saturated aliphatic species occur between 3000 and 2800 cm\(^{-1}\), and the corresponding simple bending vibrations nominally occur between 1500 and 1300 cm\(^{-1}\).

Next in our understanding is that it can take slightly more energy to excite a molecule to an asymmetric than a symmetric vibration. While this might be less intuitive, it is still a rational concept, and therefore easy to understand and accept. Again, we see a good example with the C–H stretch of an aliphatic compound (or fragment), where we observe the asymmetric C–H stretch of the methyl and methylene groups (2960 and 2930 cm\(^{-1}\), respectively) occurring at slightly higher frequency than symmetric vibrations (2875 and 2855 cm\(^{-1}\), respectively for methyl and methylene). For the most part, this simple rule holds true for most common sets of vibrations. Naturally there are always exceptions, and a breakdown of the rationale may occur when other effects come into play, such as induced electronic, spatial or entropy-related effects.

There are many other spatially related scenarios that tend to follow well-orchestrated patterns, examples being in-plane and out-of-plane vibrations, the differences between cis and trans spatial relationships, and a variety of multicentered vibrations that are defined as twisting or rocking modes. Many of these are exhibited with the C–H vibrations that occur in saturated, unsaturated and aromatic compounds. Molecular symmetry of the static or the dynamic (during vibration) molecule has a large impact on the spectrum, in addition to factors such as relative electronegativity, bond order and relative mass of the participating atoms.

Finally, while discussing the vibrational origins of infrared spectra, it is worth commenting that further complexity may be noted in the spectrum, beyond what is expected based on the fundamentals. As noted, transitions to higher energy levels, although theoretically not allowed, can occur and these give rise to overtone bands, which in the mid-infrared region occur at approximately twice the fundamental frequency for the first overtone. Higher overtones exist, typically the second (3 \(\times\) fundamental) and third (4 \(\times\) fundamental), and sometimes higher, and these are observed, with extremely low intensity, relative to the fundamental in the near-infrared spectral regions, between 800 and 2500 nm (12,500 and 4000 cm\(^{-1}\)). Other types of bands that can add complexity to a spectrum are combination bands (sum and difference), bands due to transitions from energy states higher than the ground state or “hot bands”, and bands due to interactions between a weaker overtone or combination band and a fundamental of the same or similar frequency, known as Fermi resonance bands. In the latter case, two relatively strong absorptions are observed, where normally only a single absorption is expected for the fundamental.\(^{(3)}\)

As additional functional groups are added to a basic backbone structure, forming a more complex molecule, additional bands are observed, either directly associated with the fundamental vibrations of the functional groups, or indirectly related to interactions between component
functional groups or the basic substructure. Such interactions can be severe, and result in overwhelming distortions in the appearance of the spectrum, a good example being hydrogen bonding. This will be dealt with in depth later.

3 SPECTRAL INTERPRETATION BY APPLICATION OF VIBRATIONAL GROUP FREQUENCIES

This section includes tabulated data relative to the most significant group frequencies for the most common functional groups and structural components found in organic compounds. Brief reference is also made to simple inorganic compounds, in the form of simple ionic species. More detailed listings can be found in published literature, and the reader is encouraged to acquire one or more of these reference texts. As already indicated, the use of tabulated data is only a part of the interpretation process, and other facets of the spectrum must be taken into account.

To help gain an understanding of infrared spectral interpretation, it is instructive to start at the root of most organic compounds, namely the fundamental backbone or the parent hydrocarbon structure. We shall start with the simple, aliphatic hydrocarbon, which is at the root of most aliphatic compounds. Aliphatic hydrocarbons exist in simple linear chains, branched chains and in cyclic structures – examples of the linear and branched chain scenarios were provided earlier for hexane isomers. Any one molecule may exist with one or more of these component structures. The infrared spectrum can provide information on the existence of most of these structures, either directly or by inference.

The introduction of unsaturation in the form of a double or triple bond has a profound impact on the chemistry of the molecule, and likewise it has a significant influence on the infrared spectrum. Similarly, the same is observed when an aromatic structure is present within a molecule. Infrared spectroscopy is a powerful tool for identifying the presence of these functionalities. It provides information specific to the group itself, and also on the interaction of the group with other parts of the molecule and on the spatial properties of the group. Examples of these include conjugation between a double bond and another unsaturated center, an aromatic ring or a group, such as a carbonyl (C=O), and the orientation or location of the double bond within the molecule, such as cis or trans and medial or terminal. It should be noted that cis/trans relationships are not specific to unsaturated hydrocarbons, and the terminology is referenced elsewhere, such as with secondary amide structures. Again, the associated changes in the spatial arrangement of the groups involved is reflected in the infrared spectrum as additional bands and added complexity.

As we move on to simple organic compounds, where one or more functional groups or heteroatoms are added to the molecule, we see many changes occurring in the spectrum. These result from the bonding associated with the functional group, and also local disturbances to the basic backbone spectrum that relate again to spatial changes and also to local and neighboring electronic effects. Examples of such functionalities are halogens, simple oxygen species, such as hydroxy and ether groups, and amino compounds. Carbonyl compounds, where the added functional group includes the C=O bond, also provide very profound contributions to the spectrum, and because of the wide diversity of these compounds they are best dealt with as a separate class.

A very characteristic group of compounds, from a spectral point of view, are the multiple-bonded nitrogen compounds, such as cyanides and cyanates. These typically have very characteristic absorptions, which are easy to assign, and are free from spectral interferences. The same can be said for some of the hydrides of heteroatoms, such as sulfides (thiols), silanes, and phosphines. Finally, there are other, oxygen-containing functional groups, as encountered in the nitrogen-oxy (NOx), phosphorus-oxy (POx), silicon-oxy (SiOx), and sulfur-oxy (SOx) compounds. These are sometimes more difficult to identify from first principles, and a knowledge of the presence of the heteroatom is helpful. The spectra are characteristic, but many of the oxy absorptions occur within a crowded and highly overlapped region of the spectrum, mainly between 1350 and 950 cm\(^{-1}\). Also, many of these compounds feature C=O bonding, which is common in other frequently encountered functionalities such as ethers and esters.

3.1 The Hydrocarbon Species and Molecular Backbone

In this section we include the characteristic absorption frequencies encountered for the parent hydrocarbon species and the associated backbone or substituent group. This includes aliphatic and aromatic structures. The spectral contributions are characterized, as previously noted, as C–H stretching and bending vibrations and C–C vibrations (stretching and bending), which for the most part are unique for each molecule, and are generally described as skeletal vibrations. In the case of aromatic compounds, ring C=C–C stretching and bending vibrations are highly characteristic, and are diagnostic. Likewise, the same can be said for the unsaturated carbon–carbon multiple bonding in alkene and alkyne structures.

3.1.1 Saturated Aliphatic and Alicyclic Compounds

See Table 1. The C–H stretch vibrations for methyl and methylene are the most characteristic in terms of recognizing the compound as an organic compound containing at least one aliphatic fragment or center. The bending vibrations help to tell more about the basic structure. For example, a strong methylene/methyl band (1470 cm\(^{-1}\)) and a weak methyl band (1380 cm\(^{-1}\)), plus a band at 725–720 cm\(^{-1}\) (methylene rocking vibration) is indicative of a long-chain linear aliphatic structure (note that splitting may be observed for the 1470 and 720 cm\(^{-1}\) bands, which is indicative of a long-chain compound, and is attributed to a crystallinity and a high degree of regularity for the linear backbone structure). In contrast, strong methyl bands, showing significant splitting, and a comparatively weaker methylene/methyl band indicate chain branching, and the possibility of isopropyl or tert-butyl substituents (depending on the amount of splitting, and the relative band intensities). A comparison between linear and branched chain hydrocarbons can be seen in Figures 3 and 4, where in the case of isocetane, both isopropyl and tert-butyl groups are present.

3.1.2 Unsaturated Compounds

See Table 2. As already commented upon, the saturated hydrocarbon C–H stretching absorptions all occur below 3000 cm\(^{-1}\). Any band structures observed between 3150 and 3000 cm\(^{-1}\) are almost exclusively indicative of unsaturation (C=C–H) and/or aromatic rings. The unsaturated hydrocarbons featuring C=C, with attached hydrogens, usually occur as either a single or a pair of absorptions, in the ranges indicated in Table 2. As noted, the number of bands and their positions are indicative of the double bond location and the spatial arrangement around the double bond. The position of the C=C stretching frequency does vary slightly as a function of orientation around the double bond, but it is less informative than the C–H information. The C–H out-of-plane bending is typically the most informative relative to the location and spatial geometry of the double bond, where terminal and medial double bonds may be clearly differentiated. Figure 5 provides a good example with the spectrum of 1-hexene, which contains the terminal vinyl group. Note that a fully substituted, medial double bond has only the C=C as the sole indicator of the presence of the double bond, unless the bond is conjugated with a second unsaturated site.

---

This increase in bond order produces a corresponding increase in bond strength, which in turn increases the force...
constant, \( \kappa \) (see Equation 3), supporting the Hooke’s law model described earlier.

As noted in Table 4, the position of the \( C=\text{C} \) bond is influenced by whether the group is terminal or medial. The single hydrogen of the terminal acetylene itself is very characteristic, reflecting the labile nature of the acetylenic \( C-H \).

### 3.2 Simple Functional Groups

Obviously, there is a potentially broad number of molecular fragments that can be considered to be functional groups attached to an organic structure or backbone. This section features the most simple and most common of the functional groups, \( -C-X \), i.e.

the halogens (\( X = F, \text{Cl}, \text{Br} \) and \( I \)), hydroxy (\( X = \text{OH} \)), oxy or ether (\( X = \text{OR} \), where \( R = \text{alkyl} \)), and amino (\( X = \text{NH}_2 = \text{NH} \) or \( = \text{N} \)). With the exception of the carbonyl functionality, these three basic functional groups cover most of the common occurrences in simple organic compounds. Note that for the oxy/hydroxy and amino functionalities, these are molecular fragments, and they contribute their own set of characteristic absorptions to the spectrum of the compound. In fact, the bonding between the functional group and the backbone is only one part of the overall picture used for the spectral interpretation.

#### 3.2.1 Halogenated Compounds

See Table 5. In principle, the interpretation of the spectra of molecules containing one or more halogens would seem to be straightforward. The functionality is simple, with just a single atom linked to carbon to form the group. With the polar nature of this group, one would expect the spectral contribution to be distinctive. In reality, this is not always the case.

In aliphatic compounds, the \( C-X \) bond typically possesses a unique group frequency, which may be assigned to the halogen–carbon stretching. When a single halogen is present, the determination of this group is straightforward. However, if more than one halogen is present, the interpretation is usually more complex. In such cases, the result varies depending on whether the halogens are on the same or different carbon atoms, and, if on different atoms, whether the atoms are close neighbors. This is particularly the case with small molecules, and the resultant spectral complexity arises from the fact that there is restricted rotation about the carbon–carbon bond.

Single bonds usually exhibit free rotation, which would normally mean that there are no preferred spatial orientations for the molecules. However, owing to the size of the halogen atom, relative to the carbon and hydrogen that form the backbone, the molecules tend to exhibit certain specific conformations, where the spatial interaction between neighboring halogen atoms is minimized, and each conformation provides its own contribution to the overall spectrum. It is important to appreciate that this issue of spatial orientation has an impact even on high-molecular-weight compounds, such as the polyhalogenated polymers, e.g. poly(vinyl chloride). Here preferred orientations have an impact on the crystallinity of the polymer, and in turn has a significant impact on both the spectrum and the physical properties of the material.

Another important issue to consider with halogen substituents is the high electronegativity of the halogen atom. This can have a noticeable impact on the spectrum of neighboring group frequencies, including adjacent hydrogen atoms. In such cases, significant shifting of the \( C-H \) frequencies can occur – the direction of the shift being dependent on the location of the \( C-H \), and whether the halogen adds or extracts electron density from the \( C-H \) bond – adding strengthens (higher frequency) and extracting weakens (lower frequency). The same influences can be observed with halogen-substituted carbonyl compounds, such as acyl halides and \( \alpha \)-substituted acids, where the bond strength of the carbonyl group is increased (see section 3.3). In most cases, both a shift to higher frequency and an increase in absorption strength for the band are observed.

Table 5 only presents the group frequencies for the aliphatic compounds, because no well-defined \( C-X \) absorptions are observed for halogen-substituted aromatic compounds. The presence of a halogen on an aromatic ring can be detected indirectly from its electronic impact on the in-plane \( C-H \) bending vibrations. Normally, we do not consider the in-plane bending bands to be of use because, as pointed out earlier, these occur in a spectral region that is crowded by other important group frequencies. However, in the case of a halogen-substituted ring, the intensity of these vibrations is enhanced relative

INFRARED SPECTROSCOPY

10

Introduction

For reference, it is informative to compare the intensities for these bands, between 1150 and 1000 cm⁻¹, for the spectra of toluene and chlorobenzene (Figure 7a and b).

3.2.2 Hydroxy and Ether Compounds

See Table 6 for alcohols and hydroxy compounds. The hydroxy function is probably one of the most dominant and characteristic of all of the infrared group frequencies. In most chemical environments, the hydroxy group does not exist in isolation, and a high degree of association is experienced as a result of extensive hydrogen bonding with other hydroxy groups. These hydroxy groups may be within the same molecule (intramolecular hydrogen bonding) or they most likely exist between neighboring molecules (intermolecular hydrogen bonding). The impact of hydrogen bonding is to produce significant band broadening and to lower the mean absorption frequency. The lowering of the frequency tends to be a function of the degree and strength of the hydrogen bonding. In compounds such as carboxylic acids, which exhibit extremely strong hydrogen bonding, forming a stable dimeric structure, a highly characteristic, large shift to lower frequencies is observed.

a Frequency influenced by nature and position of other ring substituents.
b Approximate center of range for the group frequency.

In special circumstances, where the hydroxy group is isolated – either because of steric hindrance effects or because the sample is in the vapor state or in a dilute solution of a nonpolar solvent – the band is characteristically narrow, and is observed at the natural, higher frequency. This absorption is important for the characterization of certain hindered phenol antioxidants, a commercially important class of compounds in the food, polymer, and formulated oil industries.

It must be appreciated that while the hydroxy absorption is singly one of the most important bands in the infrared spectrum, other vibrations are also important for the actual characterization of the compound. Alcohols exist as three distinct classes – primary, secondary and tertiary – distinguished by the degree of carbon substitution on the central hydroxy-substituted carbon, a single substitution being primary, double substitution being secondary, and triple substitution being tertiary. This is an important fact, because the chemistry and oxidation stability of the alcohol are strongly influenced by the degree of substitution. Whether an alcohol is primary (1°), secondary (2°) or tertiary (3°), may be reflected in the position of the OH stretch absorption, but typically this is determined by the other absorptions, in particular the C−O− stretching frequency. Another absorption of lower importance, but often characteristic, is assigned...
to another form of bending vibration, the out-of-plane bend or wagging vibration of the O–H. The OH bending vibrations are broadened by hydrogen bonding as is the stretching absorption, but often to a lesser extent. The differences between primary and secondary alcohols can be appreciated from Figure 8(a) and (b), where the spectra of 1- and 2-octanol are presented.

See Table 7 for ethers and oxy compounds. In some respects, ethers are related to alcohol and hydroxy compounds, where the hydrogen of the hydroxy group is replaced by an aliphatic (alkyl) or aromatic (aryl) molecular fragment. Having stated that, the overall appearance of an ether spectrum is drastically different from that of a related alcohol. This is due to the overwhelming effect of hydrogen bonding on the hydroxy group. However, many of the relationships that exist for the C–O component of the alcohol carry over to the corresponding ether. The relationships that pertain to primary, secondary, and tertiary structures remain intact. The main difference is that one now considers the bonding on both sides of the oxygen, because if carbon is on both sides, then two ether bonds exist. Ethers can exist as simple ethers (same group both sides) and mixed ethers (different groups both sides). Infrared spectroscopy is fairly sensitive for differentiating these ether functions, especially when the structures are mixed aliphatic or aliphatic/aromatic.

3.2.3 Amino Compounds

See Table 8. In some respects, the infrared spectra and the characteristic group frequencies of amines tend to

*Typically very weak, and not very characteristic in the infrared. Tend to be more characteristic in the Raman spectrum.
parallel those of alcohols and ethers. Before proceeding, there is an important distinction to be made between the nomenclature used to describe alcohol structures, compared with that used for amines. The terms primary, secondary, and tertiary are used to describe alcohols, but the substitution relates to the nitrogen, not the adjoining carbon (as with alcohols). The terminology used is \(-\text{NH}_2\) primary, \(>\text{NH}\) secondary and \(>\text{N–}\) tertiary. As before, these structural differences are important, and they strongly influence the chemistry and the reactivity of the nitrogen and the \(\text{N–H}\) group (primary and secondary). Again, the infrared spectrum is very diagnostic, and it is possible to differentiate readily the functional group structures, especially for the primary and secondary amino compounds (see Figure 9a–c for an example comparison of primary, secondary, and tertiary aromatic amines).

As with hydroxy compounds, hydrogen bonding is important, but the effect tends to be weaker than for the hydroxy group, and the overall effect on the spectrum is slightly less pronounced. This situation alters in the related ammonium and amino salts, where strong hydrogen bonding is experienced, and a corresponding broadening of the associated \(\text{NH}\) absorptions is observed.

Note that only the primary and secondary amines exhibit the most characteristic group frequencies, which are associated with the \(\text{N–H}\) bond. Tertiary amines are very comparable to ethers, and the main diagnostic information is gathered from the \(\text{C–N}\) vibrations only. An important exception is the methylamino (and dimethyl-amino) group, which like its counterpart (methoxy in ethers) has a characteristic \(\text{C–H}\) stretching vibration at lower than the normal \(\text{C–H}\) stretching frequency for methyl.

### 3.3 The Carbonyl Group

Carbonyl compounds are not only chemically important, but are also important in the interpretation of infrared spectra. The \(\text{C}=\text{O}\) absorption is almost always one of the most characteristic in the entire spectrum, and it is also most likely to be the most intense spectral feature. Table 9 provides an example listing of some of the common carbonyl frequencies as a function of the particular type of carbonyl group. In essence, a ketone is considered the root compound, with an aldehyde being a special case, where the carbonyl group is terminal, and only has one substituent, the other being a single hydrogen atom. All of the other carbonyl compounds, in a way, can be considered to be derived from the base ketone structure, where one or both alkyl (or aryl) substituents are replaced by another functionality, e.g. from a single hydroxy group, in the case of carboxylic acids, to two ether groups, as in the case of an organic carbonate.

The actual diagnostic carbonyl absorption frequency is dependent on the electronic characteristics of the substituent group, which in turn define very much the chemical characteristics and reactivity of the specific carbonyl compound. Spatial and structural factors can be important, in particular ring stress, as in the case of lactones (cyclic esters) and lactams (cyclic amides). In this case, the greater the ring stress, the higher is the carbonyl absorption frequency. In common with previous observations for a double-bonded functionality, conjugation plays an important role in the observed carbonyl frequency. This includes connection to an aromatic ring or conjugation to a \(\text{C}=\text{C}\) or another \(\text{C}=\text{O}\).
As previously discussed, a lowering of the parent group frequency is observed. This effect is important for the differentiation of certain types of carbonyl compound, in the determination of whether the carbonyl group is directly or indirectly attached an aromatic ring, e.g. the ability to differentiate aryl acetates from alky1 benzoates. In the case of the acetate, the ring is joined to the “ether oxygen” of the ester group, and is not conjugated with the carbonyl, whereas with the benzoate, the ring is directly conjugated with the group, and the carbonyl absorption frequency is correspondingly lowered.

Often, the frequency ranges for the different classes of carbonyl compound overlap, and the carbonyl frequency alone is not sufficient to characterize the functional group. In most cases, spectral information from the other component of the functional group is used for the characterization. Carboxylic acids are a good example, where the C–O, C–O–H and O–H vibrations are highly characteristic. Similarly, esters (C–O–C) and amides (C–N and N–H) are other frequently encountered examples. The frequencies provided earlier for these additional functionalities (C–O, C–N, and N–H) in general apply, although the actual observed frequencies may differ slightly, being modified by the carbonyl group. It is worthwhile returning momentarily to carboxylic acids, because they are unique, in so far as the hydroxy group has direct interaction with the carbonyl group, by the formation of a stable dimeric hydrogen-bonded structure in the condensed phase (solid and liquid). Note that this structure disappears in the vapor state. A characteristic broad feature in the range 3300–2500 cm\(^{-1}\), that overlaps the C–H stretching region, and with a secondary absorption close to 2600 cm\(^{-1}\), is observed for the hydrogen-bonded O–H of most carboxylic acids. The impact of this overlap can be appreciated by reference to the spectrum of butyric acid, provided in Figure 10. Other bands that are associated with the C–O and O–H components tend to be less pronounced, and sometimes may be overlapped with other fingerprint absorptions of the molecule. These are located in the ranges 1320–1210 cm\(^{-1}\) (C–O stretch) and 960–850 cm\(^{-1}\) (hydrogen-bonded O–H out-of-plane bending).

### 3.4 Other Functional Groups Associated with Heteroatoms

Potentially there are very large numbers of different organic-based compounds that are associated with one or more heteroatoms. These are in addition to the simple halogen- and amino-based compounds that have already been covered. A detailed discussion of such compounds is beyond the scope of this article. A few illustrative examples are included here in order to provide the reader with a feel for the spectral contributions of commonly encountered compounds that feature heteroatoms. These include triple-bonded and cumulated double-bonded nitrogen compounds, such as cyano and cyanato compounds, hetero-oxo compounds, such as nitro, sulfoxo, phosphoroxy and silicoxy compounds, and thiols and thio-substituted compounds. Many of these belong to important compound classes, and complete texts exist that focus on the spectral attributes of such compounds.

#### 3.4.1 Multiple-bonded and Cumulated Double-bonded Nitrogen Compounds

Nitrogen compounds featuring triple or cumulated double bonds, such as cyanides or nitriles (–C≡N) and cyanates (–O–C≡N\(^{−}\)), all provide a unique spectrum, typically with a single, normally intense absorption at 2280–2200 cm\(^{-1}\).

![Figure 10](image-url)
(for cyano compounds) and 2285–1990 cm\(^{-1}\) (cyanates, isocyanates, thiocyanates, etc.). The band is assigned to the stretching vibration, which is the asymmetric stretch in the case of the cumulated double-bonded compounds (the symmetric stretch is typically weak, and is not diagnostic of the group).

Double-bonded nitrogen groups, such as imino groups (\(\text{C}=\text{N}^-\)) and azo groups (\(\text{N}==\text{N}^-\)), exhibit absorptions close to the carbonyl (\(\text{C}=\text{O}\)) and alkene (\(\text{C}==\text{C}\)) double bond stretching region. While they are characteristic for the functional group, they are sometimes difficult to assign from first principles because of the overlap with other common functional groups in the region. For example, dependent on substitution or location, the \(\text{C}=\text{N}^-\) group can occur in the same spectral region as the \(\text{C}=\text{O}\) of an amide. Examples of the group frequencies for a few common multiple-bonded and cumulated double-bonded compounds are provided in Table 10.

### 3.4.2 Hetero-oxy Compounds

The group of compounds covered here feature \(\text{X}–\text{O}\) (where \(\text{X} = \text{nitrogen, sulfur, phosphorus, and silicon}\)) and \(\text{X}=\text{O}\) vibrations. In general, the characteristic absorptions span a similar range to that covered by the corresponding carbon–oxygen compounds, with most of the stretching frequencies observed within the main fingerprint spectral region (1500–400 cm\(^{-1}\)). Many of the compounds can be considered to be analogs of ethers, especially when an alkoxy group is present, featuring the \(\text{X}–\text{O}–\text{C}\) linkage. Interestingly, the nitro group (\(\text{NO}_2\)) is isoelectronic with the carboxylate group (\(\text{CO}_2\)) and both provide very similar characteristic group frequencies occurring at noticeably lower frequencies than the oxygen-containing analogs, and both provide very similar spectra for the main functional group. See Table 11 for example group frequencies for hetero-oxy compounds.

### 3.4.3 Thiols and Thio-substituted Compounds

Thiols and thio-substituted compounds, by definition, can be considered to be the direct analogs of the equivalent oxygenated compounds such as alcohols and ethers. Unlike the oxygen-containing analogs, the equivalent \(\text{C}–\text{S}\) and \(\text{C}–\text{S}–\text{H}\) stretching vibrations tend to give rise to very weak absorptions in the infrared spectrum. The \(\text{C}–\text{S}\) and \(\text{S}–\text{H}\) bonds are highly polarizable, and hence produce stronger spectral activity in the Raman spectrum than the infrared spectrum. The higher mass of sulfur, compared with oxygen, results in the characteristic group frequencies occurring at noticeably lower frequencies than the oxygen-containing analogs, as noted in Table 12 for compounds containing \(\text{S}–\text{H}\) and \(\text{C}–\text{S}\) bonds. The thiol \(\text{S}–\text{H}\) is probably the only infrared absorption that can be considered to be of use for the general characterization of these compounds, and most of the others are obtained by inference, or from knowledge of the compound type. Catenation is a unique chemical characteristic of sulfur, where the formation of \(\text{S}–\text{S}\) bonds in extended chains is common, hence the inclusion here of the \(\text{S}–\text{S}\) stretching frequencies.

### 3.5 Simple Inorganics

Characterization of compounds via infrared spectroscopy is not limited to organic compounds. Any inorganic compound that forms bonds of a covalent nature within a molecular ion fragment, cation or anion, will produce a characteristic absorption spectrum, with associated group frequencies. In a manner, certain aspects

$^a$ Typically, the first absorption is intense and broad, and the second has weak to medium intensity and is narrow. Both often exist as multiple band structures, and this may be used to characterize individual compounds.

4 THE PRACTICAL SITUATION – OBTAINING THE SPECTRUM AND INTERPRETING THE RESULTS

Up to this point, the fundamentals of interpretation have been discussed from the most basic concepts of infrared absorption by a molecular species and the impact of chemical functionality on the resultant spectrum. In many ways, this discussion has treated the molecule as a more or less isolated species, with no consideration of the physical state of the actual sample or the environment in which the molecule exists. Physical state and the molecular, chemical and physical environments have a profound effect on the infrared spectrum. As a result, it is just as important to understand and interpret these effects as it is to perform the fundamental interpretation of the functional groups from first principles.

This particular section may be one of the most important for many of the readers, because it reflects the real world, that is, taking a sample, preparing it for analysis, and making use of all of the available information on the sample and the spectrum obtained. Note that sometimes there are several options in the way that a sample may be handled for infrared analysis. It is often beneficial to consider the different options. Before we start to examine the situation it is important to understand the importance of the interpretation and to determine the real requirements. Here are some example scenarios:

1. The sample (or spectrum) is a “total unknown” and an identification is required – examples include forensic samples, environmental waste samples, or new discovery samples, where a new material has been synthesized or discovered.

2. The sample (or spectrum) is an unknown and it needs to be characterized or classified – examples include commercial applications where new additives or components are included in a material to provide a specific property; in such cases this could be considered the basis of competitive product analysis.

3. The sample generally is known but the existence of a specific chemical class needs to be determined – examples include commercial applications where new additives or components are included in a material to provide a specific property; in such cases this could be considered the basis of competitive product analysis.

4. The sample is a complete known and the interpretation is required to confirm the material composition and/or quality – examples include product quality control and the confirmation of a structure or functionality of a newly synthesized material.
There are clearly many other scenarios that can be considered, and the examples presented may cross over into more than one of these scenarios. However, the idea here is to help define a strategy for the interpretation. For the most part, this text will focus on scenarios 1 and 2, although a passing reference may be made to the others. Note also that there are two ways to address the interpretation:

- one is to attempt to assign as many bands as possible using group frequency tables;
- the other is to attempt to build up a picture using information from key spectral bands (with a knowledge of the group frequencies) and rationalizing the spectrum relative to the sample as known, and any known history, including the sample preparation and presentation technique.

The latter approach is the best way to go, and is typically far more rewarding. Also, it is seldom that all bands in the infrared spectrum of a sample can be fully or accurately assigned. There are too many ambiguities and coincidences for a definitive interpretation to be obtained from the spectra of most materials — remembering, of course, that the sample may be a mixture.

To begin, let us start from either the point where a spectrum has been generated or where a sample is presented. In practice, these are very different starting points. The latter is always preferred because with the sample in hand it is possible to gain a lot of first-hand information about nature which will ultimately help in the final interpretation. The term “unknown” is used because this is how people often view the interpretation process; however, in reality there are seldom true unknowns — in other words, the reason for the interpretation itself often provides implied information about the sample. Even if a person presents a prerecorded spectrum, it is usually accompanied by some additional information. This at minimum should include a knowledge of how the sample was prepared, whether it is a solid, liquid, or gas, or some mixed state, and maybe some physical characteristics (color, appearance, melting point/boiling point, etc.). For the benefit of presenting a complete picture, we shall assume that the sample is available and that we have the opportunity to perform additional tests and measurements on it. Further, more detailed discussions of this practical approach can be found in the literature.\(^\text{(18–20)}\)

4.1 Sample History

As noted, we are seldom dealing with a true unknown, and typical situations include the following:

- a sample of fiber taken or extracted from a particular environment;
- a contaminant removed from a material;
- a suspicious liquid found leaking out of some drums;
- a residue extracted from a surface;
- a residual liquid or solid remaining after storage or treatment of a product;
- extracted additives or components from a commercial product;
- a mass that was produced after a specific chemical reaction;
- or simply a manufactured product.

Most people can equate with these different sets of circumstances. Each one brings information about the sample.

In the case of a fiber, if it is organic, then it typically fits within certain classes of polymeric materials. It may have orientation properties, which will influence the appearance of the infrared spectrum, depending on how it is sampled, and if there is more than one fiber, then the original material may have been a blend. The environment from where the sample was taken will be important because there may be surface contaminants that may produce spurious bands in the spectrum, which may be removed by some sample pretreatment, such as washing with a solvent. Alternatively, the fiber may be coated, or degraded, thermally or by oxidation.

The characterization of contaminants is a common application for infrared spectroscopy. For this type of exercise it is necessary to know the importance of the contaminant and why it is believed to be a contaminant. Was it extracted from a liquid or solid matrix? if so, what type of matrix, and what was the composition of the matrix? Is it possible that the contaminant originated from the matrix itself, as a breakdown product? — if so, then there should be some chemical similarities or common heritage. Was it embedded within a matrix, such as a plastic/polymer film or a sheet of paper? — if so, is the contaminant itself potentially contaminated by the matrix? This is especially important for interpretation, because the matrix may have a very intense infrared spectrum of its own.

For extracted materials, such as additives removed from a polymer, it is important to know something about the polymer matrix — few extractions are 100% efficient, and it is common to have carry-over. In many such cases, the spectrum obtained reflects that of a mixture rather than a pure compound. Things to bear in mind here are what the original base polymers were, what other additives could be present, and what material, usually a solvent, was used for the extraction.
Looking at residues and residual products of a reaction is similar to the concept of characterizing a contaminant. Residues formed within products are often the result of a breakdown reaction or an unexpected interaction between components. If derived from one or more of the components, then a knowledge of all of the ingredients is essential – again we would be looking for chemically related species in the residue, and reference spectra of each of the ingredients would be important in attempting to characterize the material. In the case of a reaction product, spectra for the reactants and any solvents or substrates (catalysts, etc.) used would be helpful.

Finally, the identification of an end product from its infrared spectrum is common practice. By definition, unless the final product is a pure chemical, most manufactured products are mixtures, often featuring blended solid and/or liquid components from percentage range concentrations to trace amounts. Often at issue is how much can be identified from the interpretation of a single spectrum. It is often necessary to perform some form of preconcentration on one or more ingredients, or to perform a chemical modification to change the spectral response of one or more of the major ingredients. This latter operation may help to remove the spectral interferences from a major component for determining the presence of minor components.

4.2 Physical Characteristics of the Sample

From considerations based on the discussions in the section above, a good working knowledge of the sample allows one to determine basic information about the sample. This information can help in the determination of the best method of sampling. It can also help to indicate if any special treatments to the sample are necessary before proceeding, such as the removal of residual solvents, or the need for selective extraction, in the event that the sample has more than one phase, or is known to be a mixture. Beyond this there are other important physical characteristics of the sample that can assist the interpretation process. As indicated, physical state can be very important. For example, it has been noted that nitro compounds are isoelectronic with organic acid salts. Many simple nitro compounds are liquids, whereas simple carboxylates are usually solids.

There are, however, many other physical characteristics and attributes that can be linked to the sample and its chemistry. This in turn can be linked to important spectral features in the infrared spectrum. Two important characteristics are color and odor. Nitrogen compounds often have color associated with them, e.g. nitro-substituted compounds often have a characteristic yellow or orange color, especially substituted phenols and amines. Similarly, unsaturated nitrogen compounds, such as azo compounds, and highly conjugated olefinic compounds, such as carotenes, are similarly colored. This can be used as a guide to look for the specific functionality in the spectrum.

Likewise, odor can be a useful guide. This author is not advocating that a person should inhale the vapor of a sample directly, for obvious reasons. However, if under cautious sampling conditions a characteristic odor is detected, then this can provide a valuable insight regarding the presence of particular functional groups. Common examples are alcohols, esters, and ketones, which often possess relatively pleasant fragrances, especially when associated with some degree of unsaturation. An almond-like odor might indicate a nitro compound, benzaldehyde, or a cyano compound (caution!), a fish-like odor is often associated with amino or amido compounds, and a putrid or “bad-cheese” odor is associated with certain carboxylic acids. With time, one can build up a mental library of common odors and fragrances, and these can be very valuable for initial material screening, by helping one look for the presence of specific functional groups.

Volatile and flammability can be useful guides. Most volatile compounds tend to have a relatively low molecular weight, and they usually are unassociated. This latter point helps to rule out certain hydrogen-bonded species, such as carboxylic acids, amines, and multiple hydroxy-substituted compounds (such as glycols). If a sample is submitted for some form of combustion analysis, it is worthwhile monitoring how it burns. If it burns with a clean, bluish flame, that might indicate that the sample is oxygenated (alcohol or ether). If it has a yellow and/or smoky flame, it indicates an excess of carbon, possible unsaturation or an aromatic compound. The latter can produce a very smoky flame.

4.3 The Chemistry of the Sample

First, there are issues relating to solubility. The old adage, like dissolves like, is very appropriate. Nonpolar materials such as hydrocarbons tend to be more soluble in nonpolar solvents, such as hydrocarbons or chlorinated solvents, whereas polar materials favor solvents such as methanol and acetone, and in extreme cases their solubility may be limited to the most polar solvents, such as water. If a material is potentially identified from its infrared spectrum as a carboxylic acid or an amino compound, then it is worthwhile to check the pH. Also, it is worthwhile to check its ability to form a salt – carboxylic acids react with sodium carbonate or sodium hydroxide to form a carboxylate salt, and amines react with dilute mineral acids, such as hydrochloric acid, to form amine salts (amine hydrochlorides with hydrochloric acid).

Certain compounds react with water; examples are acid halides and acid anhydrides. Alternatively, these
compounds will react with alcohols and amines to form esters and amides. The formation of such derivatives is common practice in the identification of organic compounds, and can be extremely informative in a definitive identification by infrared spectroscopy. Other chemical modifications that can be equally informative are for the identification of olefinic or unsaturated compounds. A simple reaction with bromine (caution – use in solution, or prepare in situ) will often confirm the presence of a double bond. The reaction product can be helpful in characterizing the nature of the unsaturation, especially in the case of a cis configuration, which is often spectrally masked by other absorptions in the region.

One similar modification, which is strictly not chemical in nature, is deuterium exchange. In this case, a compound with either a labile hydroxy group or an amino group is placed in equilibrium with a deuterated solvent, such as deuterium oxide (heavy water). The replacement of the O–H in the molecule by O–D, in the case of hydroxy compounds, can help in the confirmation of the hydroxy group, and it can shift an overlapping hydroxy function from the C–H stretching and bending regions, thereby assisting in the determination of the backbone structure. Note that the shift induced by the replacement of O–H by O–D is nearly as much as 1000 cm⁻¹.

Finally, an important chemical characteristic to be understood is hydrogen bonding. The infrared spectrum is a wonderful tool for helping to monitor the presence of this phenomenon. However, one must be aware of the fact that hydrogen bonding is usually concentration dependent. If a hydroxy compound is examined in a nonpolar solvent, one should be aware that the hydroxy group spectrum, in particular bands assigned to the stretching vibration, will change shape, position, and intensity as a function of concentration. Also, diagnostically, if the hydroxy group bands do not change significantly with concentration, then this is a strong indication of intramolecular (internal) hydrogen bonding. This latter information is important in helping to determine the spatial relationships of hydroxy groups within a molecule.

The last two sections might seem to be obvious basic knowledge in the chemistry and physical properties of a material. However, just simple observations of the type described can be invaluable in determining the presence of specific functional groups when used in combination with the infrared spectrum. Likewise, the use of negative spectral information, viz. the absence of a characteristic group frequency, is equally important. For example, if a sample has an almond-like odor, but does not have a strong band between 2200 and 2000 cm⁻¹, then the compound is more likely to be a nitro compound or benzaldehyde than a cyano compound. If an aldehydic carbonyl group is absent, then the compound probably contains a nitro group.

4.4 The Infrared Sampling Method

The final appearance of the infrared spectrum is very important in the interpretation process. Where possible, it always helps to be able to study the sample as it occurs naturally, without any form of physical modification. This eliminates the possibility of any interactions, or even chemical modifications. A common method for handling solid samples is known as the compressed alkali metal halide pellet method (KBr pellet or disk method). This method of sample preparation is prone to difficulties, and it often requires a skilled operator to produce good-quality spectra on a routine basis. A poor sample technique with this method can lead to spectral artifacts and distortions, all of which can cause difficulties in the interpretation. Furthermore, some compounds may react with KBr, causing either a liberation of the halogen (oxidants) or halogen exchange (halide salts). The act of applying pressure can also change the appearance of the spectrum, especially when a material exists in more than one polymorphic form. The pressure may cause one polymorph to dominate, thereby changing the entire absorption band distribution of the spectrum. This is especially a problem with certain pharmaceutical products.

Other pretreatment methods, such as melts and cast films for solid samples, can cause similar problems. The cooling process (from melts) or the casting process can induce preferential crystallization of a particular form of the material, and sometimes preferred orientations can result. All of these effects can give rise to nonrepresentative spectra, which can cause interpretation problems.

With liquids, it is always beneficial to examine the sample as it is received. Liquid transmission cells have been used successfully in the past, but care and attention must be paid to the nature of the window material and to the cell pathlength. Low-molecular-weight materials usually require very short pathlengths in order to obtain a good-quality spectrum with most of the absorption bands on-scale. If too many bands bottom out, it is difficult to ascertain the relative intensity of certain key functional groups, and sometimes key factors, such as band splitting, may be missed. Also, if the sample is of low molecular weight, and volatile, it is important to ensure that the cell seals adequately.

In recent years, focus has been placed on reflectance methods of measurement, primarily from the surface of a sample. The most common methods are diffuse reflectance, specular reflectance and/or transfectance, and ATR. Generally, these are nondestructive methods, and require only a minimum amount of sample
preparation. The specular and transfectance methods have found greatest use with microscope-based methods of spectral measurement. Diffuse reflectance and ATR are important laboratory methods, and both lend themselves to rapid and reproducible sampling. However, both methods have an impact on the spectrum, and neither method necessarily provides a true spectrum of the sample free from some form of distortion or aberration. ATR is the simplest to handle, and its main limitation is that it provides a spectrum where the spectrum intensity across the spectrum increases as a function of wavelength. Both diffuse reflectance and specular reflectance can be the most difficult to handle, because both methods can cause severe band distortions, linked to surface and refractive index phenomena. In all three cases, the nature and the origin of the distortions are understood, and can be assigned to known physical properties. If necessary, software algorithms can be applied to correct for most of the distortions – a wavelength correction function in the case of ATR (for qualitative use), and a spectrum transformation, known as the Kramers–Kronig transform, in the case of surface reflectance distortions.

One other technique that is not so common but is important for certain “difficult-to-handle” samples is photoacoustic spectroscopy. The accessory, which also functions as the detector, provides a true absorption spectrum from a sample directly, with no sample modification. It is particularly good for samples that naturally have high absorption, such as carbon-filled materials, and for materials that are a good thermal conductor. As with ATR spectra, there is a wavelength dependence of the peak intensity across the spectrum.

The entire subject of sample handling is very broad, and generally falls outside the scope of this article. However, its impact on the final infrared spectrum and its resultant impact on the interpretation process can be very profound. Therefore, the reader is encouraged to read specific texts that address the subject in greater detail.\(^{21–23}\)

5 AN OVERVIEW TO INFRARED SPECTRAL INTERPRETATION – SOME SIMPLE RULES AND GUIDELINES

This final section is a review of the ideas presented so far as to how to go about the interpretation of an infrared spectrum. With it, there is the implied understanding that the infrared spectrum is only one source of information, and additional information is most likely required for a satisfactory analysis of the spectrum. The following are a set of simple guidelines to help a person through the early stages of rationalizing an infrared spectrum and to get to the first stages of an interpretation. However, note that this is not a definitive set of rules.

First, it is important to appreciate that there are often recurring patterns in the spectrum that are characteristic of certain classes or compounds and/or functional groups. Such patterns can be far more diagnostic in the interpretation process than merely isolated group frequencies. Examples include the overall appearance of the hydrogen-bonded hydroxy functionality, the patterns associated with unsaturation and aromativity, and the combinations of bands used to characterize different carbonyl compounds. To start, it is worthwhile to determine if the compound is organic (evidence of C–H functionality) and if there is a characteristic chain or ring associated with the compound. Having determined this, it is worthwhile to reflect on the complexity of the spectrum, and to see if one or two characteristic functionalities, associated with simple functional groups (–OH, –NH, C=O, etc.) are present. Often, the like-to-like rule applies – that is, a simple spectrum is usually indicative of a simple molecular structure, and vice versa.

If the spectrum clearly indicates multiple functionality, then be aware that mutual interaction may be occurring, and this may be causing some deviations from ideality, relative to the common group frequency assignments. Also, remember that multiple functionality might reflect a complex structure, but it might also reflect that the sample is a mixture. In both cases, an appreciation of the existence of spectral coincidences is very important. For example, a strong absorption between 1250 and 1150 cm\(^{-1}\) can be assigned to numerous types of chemical bonds, from the C–F group to the Si–O group. A careful assessment of the other spectral features, and most likely an understanding of the nature of the sample, will usually help in resolving some of these spectral coincidence situations. The use of known relative band intensities for certain functional groups can also be helpful in determining whether band overlap is occurring, and in particular whether the bands from a group are being obscured by other more intense bands. A good example is the overlap of the \(\text{cis C}–\text{H}\) out-of-plane bending vibration, which is typically overlapped by the \(-(\text{CH}_2)_n–\) rocking vibration of long-chain aliphatic compounds.

Also, if multiple functionality exists, some form of separation scheme may be in order to help determine if the sample is a mixture and, if so, to help separate some of the components. While this may not always be necessary – there are many commercial mixtures identifiable from the original spectrum – it is often required for a more definitive evaluation of a sample from its infrared spectrum. An example of such a mixture is provided in Figure 11. The spectrum of this four-component mixture can be interpreted from a knowledge of the components – acetone, methanol, dichloromethane.
INFRARED SPECTROSCOPY

Figure 11 ATR spectrum of a commercial solvent mixture containing methanol, dichloromethane, toluene and acetone. Copyright Coates Consulting.

and toluene. However, the use of separation techniques, such as water-based solvent extraction, and partial distillation can help in determining the identity of the components.

Finally, in terms of using the first-assessment rules outlined in the remainder of this section, it is important to incorporate all known chemical and physical information, including pertinent test data, such as the presence of unsaturation, which may be used to corroborate the spectral data for a suspected double bond. Remember that simple information, such as color and odor, can be equally important – highly conjugated compounds and nitro compounds often give rise to significant color, and numerous functional groups, such as esters, ketones, unsaturation, and nitro groups, have highly characteristic fragrances or odors, even in the solid state.

The following first assessment guide is based on the examination of critical spectral regions for evidence of highly characteristic molecular backbones or fragments and functional groups. An important point to remember here is that negative information, in the form of no-band regions, is extremely important, and helps to eliminate major classes of chemical compounds, thereby reducing the number of possibilities in the final interpretation.

5.1 A Quick Diagnostic Assessment of an Infrared Spectrum

5.1.1 Step 1: Overall Spectrum Appearance

Is the spectrum simple? Are there only a few main characteristic absorption bands, say less than five?

If the spectrum is simple, as defined, then the compound may be a low-molecular-weight organic or inorganic compound, such as a simple salt of a common molecular ion (carbonate, sulfate, nitrate, ammonium, etc.) or a covalent species (chloroform, dichloromethane, methanol, water, etc.). In this case, the physical properties are important – if the material is a crystalline solid, then it is most likely a salt; if it is a mobile, possibly volatile, liquid, then the latter probably applies. Note that there are always exceptions, e.g. bromoform and iodoform, simple covalent compounds, are crystalline solids (both melt at low temperatures, whereas salts do not). One other class of compounds worth mentioning here is simple polymers, such as polyethylene and polytetrafluoroethylene, both of which exhibit very simple spectra when obtained from thin films.

Are some of the bands broad? Hydrogen bonding possibly exists and can be exhibited in hydrates, water solutions, alcohols, ammonium compounds, amino compounds, etc. Note that some inorganics may exhibit a combination of both broad and very narrow bands, even for certain hydrated species. These are often related to the crystalline structure of the compound and the symmetry of certain aspects of the molecular/ionic structure.

5.1.2 Diagnostic Step 2: Testing for Organics and Hydrocarbons – Absorptions in the Region 3200–2700 cm⁻¹

Well-defined and characteristic absorptions in this region are normally characteristic of carbon- and hydrogen-containing species, and are assigned to various forms of C–H stretching.

Are there absorptions above 3000 cm⁻¹? If yes, then the compound is likely to be unsaturated (contains C=C) or aromatic. If isolated absorptions occur at 3010 and/or 3040 cm⁻¹, then the absorbing species is mostly simple olefinic unsaturation.

Is the main absorption below 3000 cm⁻¹? If so, the compound is probably aliphatic. If the main absorptions are approximately 2935 and 2860 cm⁻¹, and there are also absorptions at 1470 and 720 cm⁻¹, then the compound probably contains a long linear aliphatic chain.

5.1.3 Diagnostic Step 3: Testing for Hydroxy or Amino Groups – Absorptions in the Region 3650–3250 cm⁻¹

Hydroxy or amino groups mainly dominate this region, both giving rise to very characteristic band profiles. The presence or absence of hydrogen bonding is well delineated in this region. One other characteristic vibration that is observed in this region, which is unlikely to be confused with any other functional group, is the C–H stretch of a terminal alkyne (acetylenic compound). This exhibits a relatively narrow absorption at
3300 cm⁻¹, and is associated with a second (C≡C) band at 2200 cm⁻¹.

Is the main absorption band in the area broad? If so, the compound is probably a hydroxy or amino group. Knowledge of the presence of nitrogen or a nitrogenous base (pH or titration) helps to support an amino compound.

Are there additional moderate to intense bands in the ranges 1600–1300, 1200–1000 and 800–600 cm⁻¹? If so, the compound is likely to be a simple hydroxy compound. Remember that the simple hydrogen-bonded OH absorption of a hydroxy (alcohol) function has a very characteristic shape.

If the feature is relatively sharp and occurs between 3670 and 3550 cm⁻¹, the compound probably contains a non-hydrogen-bonded hydroxy group, often an alcohol or phenol with a sterically hindered OH group. Note also that this spectral feature is also exhibited by certain inorganics and minerals, and is indicative of a “free” OH group, either on the surface, or embedded within a crystal lattice, and free from interactions with other ions or groups.

5.1.4 Diagnostic Step 4: Testing for Carbonyl Compounds – Absorptions in the Region 1850–1650 cm⁻¹

A major band in this region usually indicates the presence of a C=O group (carbonyl compound). Note that certain C=N (imino) and N=N (azo) groups may interfere, example compounds being purines.

Is the absorption at the high end of the range, e.g. 1775 cm⁻¹ or above? If yes, the compound probably contains a reactive carbonyl, such as an anhydride, acid halide (acyl halide) or α-halogenated carbonyl, or a strained-ring carbonyl, such as a lactone, or an organic carbonate.

Is the absorption in the middle of the range, 1750–1700 cm⁻¹? If yes, the compound is probably a simple carbonyl compound, such as a ketone, an aldehyde, an ester, or a carboxylic acid.

Is the absorption at the low end of the range, e.g. below 1700 cm⁻¹? If yes, the compound is probably an amide or a carboxylate (carboxylic acid salt). Note that conjugation with another carbonyl group, or a double bond or aromatic ring, will lower the carbonyl absorption by 30–50 cm⁻¹. Therefore, conjugated aldehydes, ketones, esters, and carboxylic acids may fall into this lower end category. If conjugation with a double bond is present, then a second strong absorption should be observed nearby, between 1650 and 1600 cm⁻¹. In the case of the involvement of an aromatic ring, it is important to look for evidence of the characteristic aromatic absorptions (see Diagnostic Step 6).

5.1.5 Diagnostic Step 5: Testing for Unsaturation – Weak to Moderate Absorption in the Region 1670–1620 cm⁻¹

Note that this is not a particularly definitive diagnostic without the support of other corroborating absorptions.

A relatively narrow, weak-to-moderate absorption, normally centered around 1650 cm⁻¹, is indicative of olefinic unsaturation (C=C). A lowering of this frequency, accompanied by intensification of the band, is characteristic of conjugation with another double bond structure, such as C=C, C=O or an aromatic ring (see comments in Diagnostic Step 4).

The test for unsaturation normally involves a check for C–H peaks above 3000 cm⁻¹, and typically as a single, or possibly a pair, of absorptions (dependent on configuration of the double bond) at ~3085 cm⁻¹ and/or ~3025 cm⁻¹ – not to be confused with the multiple band situation for aromatics (see Diagnostic Step 6).

Are there single or multiple bands between 1000 and 880 cm⁻¹ (C–H out-of-plane bending)? If so, this, in combination with the 1650 and 3010 and/or 3040 cm⁻¹ bands, can be used as an assignment of unsaturation. This is either terminal (or vinyl –CH=CH₂), with a pair of bands, normally located about 990 cm⁻¹ and close to 900 cm⁻¹, or trans unsaturation (CH=CH), with a band centered around 965–960 cm⁻¹. A single band around 890 cm⁻¹, in conjunction with the other unsaturation absorptions, can indicate a vinylidene (or pendant, C=CH₂) type of olefinic double bond.

Note that a cis configuration (CH=CH) is sometimes hard to characterize, because the normally characteristic C–H out-of-plane bending is broad, with only a moderate absorption, and occurs in a region (around 700 cm⁻¹) where it can overlap with absorptions from other structural components, such as long-chain aliphatics, aromatics, and halogen compounds.

5.1.6 Diagnostic Step 6: Testing for Aromatics – Well-defined Absorptions in the Region 1615–1495 cm⁻¹

One, but typically two, sets of bands in the region, with one set around 1600 cm⁻¹ and the other around 1500 cm⁻¹, are consistent with an aromatic compound. Sometimes the absorptions occur as single bands, at other times one or more of the band sets may appear split, as an asymmetric doublet. This assignment is usually confirmed by the presence of other bands in the spectrum.

Are there a series of weak-to-moderate absorptions in the region 3150–3000 cm⁻¹, which can be assigned to aromatic C–H stretching? These usually support the presence of the 1600/1500 cm⁻¹ aromatic ring bands (see Diagnostic Step 2).
For simple aromatic compounds, a series of weak absorptions may be observed between 2000 and 1700 cm\(^{-1}\). These are multiple combination bands that are noticeably weak, and are typically not to be confused with an isolated weak carboxyl absorption.

The C–H bending vibrations can also be used to support the presence of an aromatic structure. If there are medium-to-strong absorptions, sometimes more than one, between 850 and 670 cm\(^{-1}\), these can be assigned to C–H out-of-plane bending on an aromatic ring. These support the assignment of the 1600/1500 cm\(^{-1}\) bands, and the locations of the bands are often indicative of the nature of the substitution of the aromatic ring. For simple structures, it is possible to differentiate mono-, di- (ortho, meta and para), and certain poly-substitutions. Note that a single, strong band may support simple ortho (around 750 cm\(^{-1}\)) or para (around 830 cm\(^{-1}\)) substitution.

Many organic compounds have multiple band structures in the region 1150–950 cm\(^{-1}\). The in-plane C–H bending vibrations of aromatic compounds typically occur in this region, and can exist as complex band structures (multiple, well-defined bands). They tend not to be diagnostic for many compounds because of conflict and overlap with other functional group absorptions, including some skeletal (backbone) vibrations. However, they are clearly observable in simple hydrocarbons as weak-to-moderate absorptions, and in halogen-substituted aromatic compounds (such as chlorobenzenes) as characteristic strong absorptions.

5.1.7 Diagnostic Step 7: Testing for Multiple Bonding (Often with a Bond Order of 2 or Higher) – Absorption in the Region 2300–1990 cm\(^{-1}\)

Multiply bonded nitrogen compounds and cumulated multiple bond compounds, such as cyanides (nitriles), cyanoates, isocyanates, thiocyanates, and diazo compounds, exhibit characteristic absorptions in the region 2300–1990 cm\(^{-1}\). Cyanide absorptions vary from weak to moderate to strong, depending on the nature of other substituents in the molecule. Conjugation, including substitution on an aromatic ring, modifies the intensity of this absorption.

If the absorption band is extremely strong, the group is more likely to be a three-center functionality, such as a cyanate, an isocyanate, or a thiocyanate.

Acetylenes and alkyne substituents also exhibit a weak-to-moderate absorption within the same spectral region. If the acetylenic function is internal (medial), then the absorption can be extremely weak. However, a terminal alkyne group (C≡C) band may have moderate intensity, and this is supported by a characteristic C–H stretching absorption around 3310 cm\(^{-1}\). A relatively low-frequency C–H bending vibration around 630 cm\(^{-1}\) also confirms the terminal alkyne vibration.

Metal carbonyls have unique bonding, where the bond order between the carbon and oxygen is between two and three, and where the additional electrons are provided by d or back-bonding from the accompanying transition metal atom. The multiply bonded CO group provides an extremely intense absorption band close to 2000 cm\(^{-1}\) (typically between 2100 and 1900 cm\(^{-1}\)), the actual position of the band(s) and the complexity of the bands being dependent on the structure of the compound.

Note that an isolated weak-to-moderate intensity absorption above the specified region, and typically between 2700 and 2400 cm\(^{-1}\), is not normally associated with a multiply bonded compound. These absorptions are usually from hydride vibrations, such as from silanes (Si–H), thiols and sulfides (S–H), phosphines (P–H), arsines (As–H), boranes (B–H), etc. Knowledge of the existence of the accompanying heteroatom helps in the assignment of the X–H bonds in these compounds.

This concludes the summary data for a first-pass assessment of an infrared spectrum, based on the most common and characteristic group frequencies. The technique is not foolproof, but for many simple compounds, if one systematically applies the diagnostic tests on the spectrum from a sample, as presented above, it is possible to gain some understanding of the chemical functionality. It is always hoped that more information can be gained from the sample, either by first-hand knowledge or by asking questions, or by performing additional tests. Once a basic interpretation is accomplished, and the sample is broadly characterized, it is recommended that reference spectra are used to try to obtain a more exact match to the sample. Always bear in mind that the sample could be a mixture, such as a commercially formulated/compounded material. In such cases, an exact match may not be possible, unless the reference spectrum exists for the formulation.

1 Introduction

Analytical techniques that combine liquid chromatography (LC) and infrared (IR) spectroscopy have been developed primarily to permit specific detection and/or identification of sample constituents. LC is an important and extensively used method for the separation of mixtures into their individual components. IR spectroscopy is very useful for the characterization of functional groups and has strong compound-identification capabilities which are especially suited for the differentiation of structural isomers. Over the past years the coupling of LC and IR spectroscopy (LC/IR) has been accomplished by two different approaches. The first and simplest approach is to use a flow cell through which the effluent from the LC column is passed while the IR spectra are continuously measured. The merits of flow-cell IR detection include ease of operation, real-time detection and low maintenance, but its main disadvantage lies in the significant IR-absorption of the solvents commonly used in LC. These absorptions seriously limit both the detection sensitivity and the obtainable spectral information. The second approach involves elimination of the LC solvent prior to IR detection. In this approach an interface is used to evaporate the effluent and deposit the separated compounds onto a substrate suitable for IR detection. The primary advantages of solvent-elimination LC/IR are the possibility to obtain full spectra of the analytes and the considerably enhanced sensitivity when compared to flow-cell detection. Unfortunately, common LC solvents, and particularly aqueous eluents, are not easily removed and therefore the evaporation interfaces are often rather complex. This article reviews the developments, practical aspects, applications and current status of LC/IR, covering both coupling approaches. It follows that despite the unfavorable detection limits, flow-cell LC/IR can be useful for the specific and quantitative detection of major components of mixtures. However, solvent-elimination-based IR-detection should be used when small amounts of sample constituents have to be characterized with a high level of confidence. In general, the practical use of IR detection in LC is still limited, but the advent of various (commercial) flow-cell and interface designs shows that LC/IR is more and more being recognized as a feasible and rewarding technique.

1 INTRODUCTION

IR spectroscopy has a high potential for the elucidation of molecular structures. The IR spectrum of a polyatomic molecule is based on molecular vibrations, each specifically dependent on atomic masses, bond strengths and intra- and intermolecular interactions. As a consequence, the entire IR spectrum of an organic compound provides a unique fingerprint, which can be readily distinguished from the IR-absorption patterns of other compounds including isomers. In other words, when reference spectra are available, most compounds can be unambiguously identified on the basis of their IR spectra. Moreover, characteristic absorption bands can be used for compound-specific detection.

LC is a powerful and versatile separation technique, which can handle a wide range of sample types and compound classes. Because of the widespread use of LC and the (growing) need for analytical procedures that provide confirmation and/or identification of sample constituents, much effort has been – and still is – devoted to the coupling of LC with spectrometric techniques such as mass spectrometry (MS), IR and nuclear magnetic
resonance (NMR) spectroscopy. Today, with modern Fourier transform infrared (FTIR) instrumentation routinely available, spectra can be recorded from nanogram, or even picogram, amounts of pure substance so that IR detection, in principle, is suited for molecular recognition at analyte levels frequently met in LC. Unfortunately, because of the (spectral) characteristics of the mobile phase, the coupling of LC and IR spectroscopy (LC/IR) is not straightforward and often requires the construction of special flow cells or the development of rather complex interfaces. Therefore, compared with other LC detection modes such as ultraviolet/visible (UV/VIS) absorption spectroscopy or MS, the use of IR detection in LC is still rather limited. Nevertheless, progress in interfacing techniques during the last decade has brought LC/IR to a stage of analytical utility which suggests that LC/IR may well become a commonly available and applied technique.

2 COUPLING MODES AND OPERATING PRINCIPLES

In the first LC/IR systems\(^1\) flow cells were used in a fashion analogous to LC with on-line UV/VIS absorption detection. In order to circumvent interfacing difficulties related to the IR absorptions of the mobile phase, in 1979 Kuehl and Griffiths\(^3\) developed the first solvent-elimination based LC/IR set-up in which the eluent is evaporated prior to IR detection. Since then two approaches can be discerned in LC/IR, namely, the flow-cell approach and the solvent-elimination approach. In the contemporary practice of LC/IR both approaches are applied, although the detection limits and spectral information obtained with either approach may differ considerably. The principles, applications, merits and limitations of flow-cell and solvent-elimination LC/IR have been reviewed in a number of books and papers.\(^4\)–\(^8\)

2.1 Flow-cell Approach

The simplest way to couple LC and IR is to let the column effluent pass directly through a flow cell suited for IR measurements. The IR absorption of the LC effluent is continuously monitored and spectral data are collected on-the-fly and stored throughout the chromatographic run. During or after the run, the spectra and/or IR chromatograms are computed and absorption due to the mobile phase is subtracted. In a flow-cell design, band broadening caused by detection is easily minimized.

Unfortunately, the absolute sensitivity of IR spectroscopy is relatively poor compared to spectrometric techniques like MS, UV/VIS and fluorescence spectroscopy. Moreover, solvents suited for LC generally have many absorption bands in the IR region, which leads to serious limitations of flow cell LC/IR interfacing. Firstly, absorption bands of analytes may be obscured by eluent absorptions. In other words, in flow-cell LC/IR, the spectral information that can be obtained is limited and depends on the window provided by the mobile phase used. Moreover, ill-considered subtraction of solvent absorption bands may lead to the erroneous conclusion that there is no absorption of the analyte in the corresponding spectral regions. Secondly, gradient elution can hardly be applied as the changing composition of the mobile phase frustrates proper subtraction of the background. To some extent, the second derivative of a spectrum can be used to compensate for this problem, but accurate spectral correction is virtually impossible. Thirdly, the pathlength of the flow cell has to be limited to ensure a certain spectral window and sufficient energy reaching the IR detector. For organic solvents commonly used in LC/IR, the effective pathlength rarely exceeds 1 mm which, bearing in mind Beer’s law, seriously reduces the analyte detectability. For aqueous eluents, the largest tolerable pathlength is even shorter. As can be seen from the spectrum of water in Figure 1, most of the mid-IR region between 4000 and 1000 cm\(^{-1}\) is opaque, even at a very short pathlength of 10 µm. It implies that a practical combination of reversed-phase liquid chromatography (RPLC) and IR via a transmission flow cell is restricted to specific applications. Finally, the use of signal averaging to improve the signal-to-noise ratio (S/N) of the spectra is limited owing to the short time that is available for analysis under dynamic conditions. Occasionally, the principle of stop-flow can be used to enhance the S/N without too much loss in chromatographic performance.

The choice for a certain mobile phase and flow-cell properties is primarily determined by chromatographic considerations and the desired spectral information. In principle, the spectral window of the solvent can be very small for quantitative analysis as the measurement of a single wavenumber, e.g. the band maximum, is

![Figure 1](https://example.com/figure1.png)
sufficient. Contrary, qualitative information desires IR transparency over a much wider spectral region in order to determine the presence or absence of functional groups, or to identify a compound by its IR fingerprint region (1300–600 cm$^{-1}$). Obviously, the spectral window of the mobile phase is inversely proportional to the cell thickness and thus, an excess of sensitivity can be traded for more spectral information and vice versa. The experimental parameters in LC/IR are, therefore, a compromise between chromatographic and spectroscopic considerations giving maximum cell thickness and solvent transparency.\(^{(5–8)}\)

In order to minimize the problems associated with eluent absorption, the choice of the solvent in flow-cell LC/IR is generally restricted to chlorinated alkanes and deuterated solvents. These solvents leave relatively wide windows in the spectrum, although even these eluents inevitably obscure parts of the spectral functional group region (4000–1300 cm$^{-1}$) and the fingerprint region. The use of a small percentage of a more polar modifier in the eluent, as is quite common in normal-phase liquid chromatography (NPLC), may already prohibit effective detection. Owing to the short optical pathlength, the absolute limit of detection in on-line LC/IR often is in the order of a few micrograms, which implies that analyte concentrations of 1–10 g L$^{-1}$ have to be injected to obtain identifiable spectra.

Tran et al.$^9$ proposed a completely different flow-cell LC/IR technique with, potentially, higher sensitivity. Different from the conventional way of measuring the IR absorption over a certain wavenumber region, this technique, called IR thermal lens spectrometry, is based on the measurement of the temperature rise that is produced in an illuminated sample by non-radiative relaxation of the energy absorbed by molecules upon IR laser excitation. Detection is carried out either directly, i.e. at a specific wavelength where only the analyte of interest absorbs, or indirectly, i.e. at a wavelength where only the mobile phase absorbs. Obviously, no spectral information is obtained with this quantitative technique, and the wavenumber region that can be covered with IR-tunable lasers is limited.

In conclusion, flow-cell IR detection is not a widely applied technique in LC as result of the interference of absorption bands of the mobile phase and the limited sensitivity of IR spectroscopy. Applications largely focus on dynamic systems where low detection limits are not crucial and solvents appropriate for IR detection can be selected more or less freely, that is, without having unacceptable detrimental effects on the analytical performance. Examples of such techniques are gel permeation chromatography (GPC), also referred to as size-exclusion chromatography (SEC), and flow-injection analysis (FIA). An important feature of the flow-cell LC/IR technique is the ability to monitor the elution of compounds with specific structural characteristics, i.e. functional groups. Besides, apart from regions of solvent opacity, spectra can be obtained instantaneously from any point in a chromatographic peak.

### 2.2 Solvent-elimination Approach

The compatibility and time-domain difficulties connected to flow-cell IR detection can be circumvented by coupling LC and IR spectrometry via a substrate suitable for IR detection. In this indirect approach, the eluent is eliminated and the chromatographically separated compounds are immobilized on the substrate prior to the collection of IR spectral data. The immobilization of the chromatogram is accomplished by using an interface which evaporates the eluent and continuously deposits the column effluent onto the moving substrate. In this way, interference-free IR spectra of the deposited compounds can be recorded independently from the LC conditions and the sensitivity of the FTIR spectrometer can be fully exploited. A schematic of a solvent-elimination LC/IR set-up is depicted in Figure 2.

Besides the possibility to acquire full spectra, there are some additional advantages of the solvent-elimination approach with respect to flow-cell IR detection. By careful control of the interface performance and the speed of the substrate, concentrated deposits may be obtained which will enhance analyte detectability. Spectral analysis can be performed without any time constraints since the chromatogram is stored on the substrate. This implies that signal averaging can be used and analyte spots can be analyzed repeatedly. For instance, after rapid screening of the deposited trace applying low spectral resolution and only one scan per spectrum, high-resolution spectra with a high S/N can be recorded for a few interesting parts of the chromatogram. Moreover, spectrometric analysis of the stored chromatogram in principle can be carried out at any convenient time or place, which may be helpful when suitable IR facilities are limited and spectrometers have to be shared.

**Figure 2** Schematic representation of a set-up for solvent-elimination LC/IR: LC, liquid chromatograph; IF, interface; Sub, deposition substrate; T, transfer; S, spectrometer.
Evidently, the solvent-elimination approach to LC/IR is (technically) more complicated than on-line IR detection. It requires an interface which should adequately effect the evaporation of the eluent and, at the same time, maintain the chromatographic resolution during the deposition process. In this respect, the LC flow rate, the composition of the eluent, the nature of the analytes and the substrate material are important factors. For example, small volumetric flows of a volatile solvent may be readily evaporated, while rapid elimination of aqueous eluents will require an interface with enhanced solvent-evaporation power. Elimination of the eluent may also be hampered by the presence of nonvolatile additives such as buffer salts. Next to eluent evaporation, ideally the interface also should provide compound deposition into narrow spots in order to minimize band broadening and achieve optimum IR sensitivity. However, complete eluent evaporation and compact analyte deposition may well be irreconcilable goals. Therefore, in solvent-elimination LC/IR reduced flow rates, nonbuffered eluents and/or eluents with a low (or even zero) water percentage are frequently used.

The compounds analyzed by solvent-elimination LC/IR, of course, should be considerably less volatile than the eluent to accomplish their deposition. Since LC is used for nonvolatiles in particular, this condition is generally met. The quality of the used substrate should not be affected by either the eluent or the deposited compounds. The substrate also must be compatible with the selected IR mode without introducing additional interferences. Furthermore, the physico-chemical properties of the substrate may influence the efficiency of analyte immobilization. For instance, residual eluent easily spreads over a substrate with a hard and smooth surface, while it may be effectively sorbed by a powder.

During the last decades, the combination of LC and IR via solvent elimination has been pursued by several research groups, which designed quite a number of different interface concepts with varying success. The common goal of all these LC/IR systems is to sensitively acquire IR spectra of mixture constituents that are free from spectral interferences and can be used for identification purposes. Through the years, the IR detection limits obtained with solvent-elimination LC/IR have improved gradually from the microgram to the low- or sub-nanogram range. Despite the progress, today there is no single “perfect” solvent-elimination interface available: every described system has its specific limitations with respect to, for example, flow rate, composition of the eluent and/or achievable sensitivity. The research activities in the field, which until now have been dominated by the problem of simultaneous eluent-evaporation and compound-deposition, are still on-going. Nevertheless, during the last years, several new commercial interfaces based on the solvent-elimination approach have been introduced.\textsuperscript{10,11}

### 3 FLOW-CELL TECHNIQUES

#### 3.1 Cell Types and Infrared Detection Modes

A variety of flow cells, differing in optical material, pathlength and cell volume, is available for LC/IR detection purposes. The cells, including corresponding beam condensing optics, generally fit in the standard optical bench of the IR spectrometer. The distance between the flow cell, i.e. the IR spectrometer, and the LC system is kept as short as possible in order to minimize deterioration of the chromatography. As noted in section 2.1, the selection of a certain cell type and, particularly, the optical pathlength, depends on the required information.

The choice for a specific window material is mainly determined by the properties of the LC eluent and the spectral region that has to be monitored. A fully IR-transparent material such as potassium bromide (KBr), for instance, cannot be used with RPLC. Instead, more expensive water-insoluble materials such as calcium fluoride and zinc selenide (ZnSe) have to be chosen. The optical and physical properties of some commonly used IR-window materials are presented in Table 1. In all cases, in order to obtain an identifiable IR spectrum a minimum amount of analyte has to be present in the

detection cell during the time of measurement. According to Beer’s law, the minimum identifiable concentration decreases when the pathlength of the cell is increased. However, extending the pathlength also results in an increase of the eluent absorbance, thus limiting the spectral window. Commonly, the volume of the flow cell has to be minimized to such an extent that only a small part (1% or less) of an LC-peak volume will fill the cell. Obviously, this places a significant limitation on the obtainable sensitivity. Through the use of microbore LC columns, the volume of the flow cells and LC peaks can be made more compatible and, for that reason, micro-LC/IR is often preferred. Besides a reduced solvent consumption, microbore LC may also offer higher peak concentrations in the cell. At the same time, however, it should be noted that the sample capacity (both in mass and volume) of micro-LC columns is rather limited.

Two types of commercially available flow cells can be distinguished for LC/IR: transmission cells and attenuated total reflection (ATR) cells. The principle of a transmission flow cell is depicted in Figure 3. The basic part of the cell consists of an IR-transparent cavity or two IR-transparent windows separated by a metal spacer. The optical set is mounted into a metal body between flexible rings to prevent breakage. The LC effluent enters and exits the cell via capillary tubes connected to an assembly of universal fittings and the IR beam passes perpendicularly through the LC flow. Additional equipment can be purchased for operation at elevated temperature and pressure. Zero-dead-volume (ZDV) flow cells for IR detection have been developed to minimize the volumes needed to connect the cell to the column, which is very important when microbore LC is used. In this type of cell the LC effluent is directly led into the cavity of the optical element (Figure 4). Flow cells, micro-flow cells and ZDV-cells can be purchased in many variations, rigid and demountable, differing in window material, pathlength (0.001–0.5 mm) and internal volume (0.1–10 µL). Micro-cells are generally used in combination with a beam condenser to obtain a sufficiently high energy throughput and thus enhance the S/N of the recorded signal and/or spectra.

The second type of flow cell is based on the phenomenon of ATR and is called cylindrical internal reflectance cell or CIRCLE® cell. The principle of the CIRCLE® cell is depicted schematically in Figure 5. The cell consists of a cylindrically shaped IR-transparent rod crystal with cone shaped ends that is incorporated in a boat-type cell body made of stainless steel (SS) or glass. The effluent of the LC column flows around the optical crystal while the interrogating IR beam enters the crystal at one end, reflects off the internal surfaces of the crystal and then exits at the other end. The cell body fits into a small optical bench with special input and output optics. Several crystal materials can be used but ZnSe is commonly preferred because of its high IR transparency, high

refractive properties and insolubility in water. CIRCLE® cells can be equipped with heating or cooling jackets too. The cell design tends to involve a relatively large sample volume and efforts have been made to reduce the internal volume of CIRCLE® cells to 1–25 μL in order to allow their efficient application in LC. The effective pathlength of a CIRCLE® cell is defined by the number of reflections in the optical element and, therefore, sensitivity can be enhanced by using longer optical elements. These, however, also imply an increased cell volume and, thus, extra broadening of the LC peaks. CIRCLE® cells cannot be used for quantification in a straightforward manner since the penetration depth of the IR radiation in the LC eluent is limited (typical 1–5 μm) and wavelength dependent. Special algorithms are used to compensate for this.

### 3.2 Use in Liquid Chromatography

As outlined in the previous sections, flow-cell IR detection is not the principal choice in LC. Yet, it is a valuable alternative and additional method to obtain specific quantitative and structural information on analytes. In view of the relatively poor sensitivity, IR detection is restricted to applications in which low detection limits are not required. In GPC, for example, column capacities and sample concentrations are usually high. Gel permeation chromatography/infrared (GPC/IR) is well suited for the characterization and quantification of compositional changes throughout a (bio)polymer mass distribution. Besides, the structural differences between the polymer components (usually homologues) often are small which implies that one or two spectral windows will suffice for specific detection.

Applications of on-line LC/IR, including automatic subtraction of the solvent background, had already been described in the mid-1970s. Injected amounts at sub-microgram level were found to be feasible for detection in both NPLC and RPLC separations. In subsequent studies, Taylor et al. demonstrated that microbore LC (column i.d., less than 1 mm) offers improved sensitivity compared to conventional LC (column i.d., 4.6 mm) because of the higher sample concentration in the detector cell. Furthermore, use of halogenated hydrocarbons as eluent was shown to offer better spectral specificity owing to the higher IR-transparency of these solvents. A reasonable number of applications of flow cell LC/IR in a variety of disciplines has been developed since. Saunders and Taylor, for example, applied online GPC/IR with tetrahydrofuran (THF) as mobile phase for the determination of the nitrogen content of cellulose nitrates. A cylindrical micro flow cell with a pathlength of 1 mm and an internal volume of 4 μL was employed in combination with a beam condenser. The extinction of the O–N–O asymmetric stretching band was used for the quantification of primary and secondary carbon nitration. An improved resolution and quantification was achieved by spectral derivatization. On-line GPC/IR is also a viable analysis method in the polymer field. One method employs high-temperature GPC with flow-cell IR detection to characterize the molecular weight distribution of high-density polyethylenes. Tri- and dichlorobenzene were used as mobile phase as these solvents do not exhibit interfering absorption in the CH₂-stretching band region (3000–2700 cm⁻¹). Furthermore, a quartz flow cell with a relative long pathlength of 1 cm could be used in order to enhance the sensitivity. The method compares favorably with gradient elution fractionation combined with ¹³C-NMR spectroscopic characterization.

The strong IR absorption of water, methanol and acetonitrile, limits the application of on-line reversed-phase liquid chromatography/infrared (RPLC/IR) to the analysis of samples with relatively high analyte concentrations, such as wines, beverages and cellulose solutions. Various examples of this type of analysis have been described in the literature. Recent applications are the identification and quantification of sucrose, glucose and fructose in soft drinks, and the specific analysis of monosaccharides, alcohols and organic acids in wine. In both studies, separations were achieved with ion-exchange columns using an aqueous eluent. IR detection was performed with a 25-μm pathlength flow cell and minimal identifiable concentrations of typically 1 g L⁻¹ were obtained.

When a high sensitivity or selectivity is required, conventional RPLC solvents cannot be used with IR flow cells. Therefore, alternative methods have been developed to circumvent the IR-opacity problems imposed by the aqueous mobile phase, while maintaining the advantages of on-line detection. One approach is the extraction of the analytes into a more IR-transparent solvent. Another approach is the use of deuterated solvents which virtually have the same chromatographic properties but do not absorb in the spectral region of interest. An example of the first method is the dynamic extraction of the analytes from the aqueous effluent into chloroform or carbon-tetrachloride. The on-line liquid–liquid extraction (LLE) is carried out in an extraction coil followed by continuous separation of the aqueous and organic phases by a hydrophobic membrane. Subsequently, the organic phase, carrying the extracted analytes, is monitored in a common IR flow cell. A basically different post-column extraction method has been developed by Messerschmidt. In this method, the RPLC effluent is diluted with water, and the analytes of interest are trapped on several small solid-phase extraction (SPE)
columns. These columns are dried with a flush of nitrogen, and sequentially eluted with a small volume of tetrachloromethane into an IR flow cell allowing the individual spectra of the analytes to be recorded. An additional advantage of this method is the improved minimal identifiable concentration as a result of analyte concentration on the SPE column. This technique has been successfully applied by DiNunzio\(^{(21)}\) for the separation and identification of active compounds and degradation products in pharmaceutical samples.

In on-line LC/IR, deuterated solvents can be attractive substitutes for conventional (hydrogenated) solvents. The absolute absorbance of deuterated solvents is usually smaller and, more importantly, their IR absorption bands are shifted to different spectral regions. Additionally, deuterated solvents and their hydrogenated counterparts show very similar elution properties. With respect to on-line extraction procedures, the use of deuterated eluents has advantages in terms of simplicity, speed and maintenance of the chromatographic resolution. A major drawback is their high price. A detailed study on the utility of deuterated eluents in micro-column RPLC, NPLC and GPC with flow-cell IR detection was carried out by Fujimoto et al.\(^{(22)}\) It follows that the problem of interfering solvent absorption bands can be (partially) solved by a deliberate choice of a deuterated eluent. Chen and Kou,\(^{(23)}\) for instance, used deuterated methanol and water instead of the nondeuterated solvents to overcome the strong interfering absorptions that hinder the effective detection and quantification of lipid fractions by on-line LC/IR. Remsen and Freeman analyzed proteins using on-line gel permeation chromatography/Fourier transform infrared (GPC/FTIR) with a deuterium oxide eluent to remove water and other detection-interfering low-molecular-weight compounds and to achieve a rapid hydrogen exchange.\(^{(24)}\) Amounts of 50 µg per protein could be detected in the amide-I region between 1600 and 1300 cm\(^{-1}\), and important information on the protein conformation could be obtained.

### 3.3 Use in Flow-injection Analysis

FIA is a well-established analytical technique, based on the automated injection of a series of samples in a continuous carrier stream. In FIA various detectors are used, mainly for quantitative purposes. Amongst these detection modes, flow-cell IR is not a frequent choice because of the interfering solvent absorptions and the relative poor sensitivity compared to UV/VIS and fluorescence detection.\(^{(25)}\) In several cases, however, on-line flow-injection analysis/infrared (FIA/IR) is an appropriate alternative for the rapid determination and quantification of a specific analyte in a simple mixture. In FIA, there is no need for an eluting solvent and, therefore, in contrast with LC, a carrier solvent suitable for IR detection can be selected quite easily. In this respect, FIA/IR has a wider application range than LC/IR. Still, the flow cells used in FIA/IR are not different from the ones used in LC/IR and the resemblance in detection approach is evident. Commonly, FIA/IR is applied for single-component analysis but since IR spectra comprise a range of absorption frequencies, multi-component analysis can in principle be carried out as well. Obviously, the IR absorption bands of the carrier should not spectrally interfere with the marker band of each analyte.

Guzman et al.\(^{(26)}\) compared the characteristics of transmission and CIRCLE\(^{®}\) cell detection in FIA/IR for multicomponent analysis of ternary solvent mixtures. With tetrachloromethane as carrier, the transmission cell provided better sensitivity in the continuous-flow mode. The shorter effective pathlength of the CIRCLE\(^{®}\) cell was compensated for by applying the stopped-flow technique which allowed data averaging and, thus, enhancement of the S/N of the ATR spectra. Analyte concentrations of 1–2% (v/v) could still be measured.

The principles and applications of flow-cell FIA/IR have been studied extensively by the group of de la Guardia.\(^{(27–33)}\) The effects of flow rate, injection volume, cell volume and optical pathlength on the performance of the FIA/IR analysis of o-xylene in solutions of hexane, were investigated.\(^{(29)}\) Further optimization was achieved in the development of a method for the automated determination of benzene in gasoline.\(^{(30)}\) In a further study, incorporation of an analyte-enrichment step was proposed to improve the detection limits of on-line FIA/IR.\(^{(31,32)}\) Preconcentration was carried out by trapping the analytes on an SPE cartridge. After drying of the cartridge with nitrogen gas, the analytes were eluted with dichloromethane and detected by IR transmission spectroscopy using a micro flow cell. For aqueous solutions of the pesticide carbaryl and its major metabolite 1-naphthol, detection limits of 0.36 mg L\(^{-1}\) and 1.6 mg L\(^{-1}\), respectively, were obtained after preconcentration of 100-mL samples. Quantification was achieved by specific detection of the bands at 1744 cm\(^{-1}\) (carbaryl C=O) and 1276 cm\(^{-1}\) (1-naphthol C–O) (Figure 6). FIA/IR is also a useful alternative for the quantitative analysis of mineral oil and grease.\(^{(33)}\) Analogous to the International Organization for Standardization (ISO) procedure for the quantitative analysis of mineral oil in water and soil, this method is based on measurement of the aromatic, olefinic and aliphatic C–H stretching bands in the 3200–2700 cm\(^{-1}\) region. The samples were extracted with tetrachloromethane by LLE or microwave-assisted extraction. Next, the extracts were analyzed by FIA/IR at a sampling frequency of 60 h\(^{-1}\) using a quartz flow
cell with a 10-mm pathlength. The detection limit was 1 mg L\(^{-1}\) when 300 µL of the extract was injected.

Miller et al.\(^{35}\) used FIA/IR for the simultaneous detection of succinylcholine chloride and bethanechol chloride, two pharmaceutically important compounds. The compounds were specifically monitored at 1075 cm\(^{-1}\) and 953 cm\(^{-1}\), respectively, using a CIRCLE\(^{35}\) cell. The detection limit was about 0.02% (w/v) at a throughput of 60 samples per hour. FIA/IR was also applied to the quantification of acetylsalicylic acid, caffeine and paracetamol in pharmaceutical formulations.\(^{35,36}\)

A chlorinated solvent the extinction of a characteristic absorption band could be measured for each of the analytes in the 1800–1500 cm\(^{-1}\) region. Commercially available flow cells with an optical pathlength of 0.117 mm (5 µL) or 0.17 mm (7.2 µL) were used. Two FIA/IR methods for automated analysis in clinical and process chemistry have been developed by Kellner et al.\(^{35,36}\)

The first method aimed for the determination of glucose and urea after on-line enzymatic digestion to gluconic acid and ammonium carbonate, respectively. A 25-µm pathlength transmission cell was used to monitor the aqueous flow from the enzyme detector. The performance of the system was satisfactory for relative clean samples such as standard solutions, fruit juices and soft drinks. However, for routine application, for example in blood analysis, further improvement of the reproducibility is still required. The second FIA/IR method was used to determine the amylglucosidase activity during starch hydrolysis processes. The IR flow cell (pathlength, 49 µm) was constructed of two different window materials in order to compromise between high transparency (ZnSe) and low reflectivity (calcium fluoride). Because of the high viscosity of the starch solutions, a stopped-flow method was used to obtain maximum reproducibility and sensitivity. The changes in the IR-spectra of the process mixture appeared to be directly correlated with the enzyme activity.

4 SOLVENT-ELIMINATION TECHNIQUES

4.1 Deposition Substrates and Infrared Detection Modes

The solvent-elimination approach in LC/IR involves the use of an eluent-evaporation interface that deposits the LC-separated compounds onto an IR-compatible substrate. With most described set-ups, after immobilization of one or more chromatograms, the substrate is transferred to the IR spectrometer where spectra from the deposited spots are recorded. The deposited traces on the substrate may be moved (stepwise) through the interrogating IR beam so that, when scanning is complete, continuous IR chromatograms can be reconstructed by computer software. In some designs, IR detection is executed during the immobilization process, within 5–20 s after deposition, allowing spectra to be obtained in real time. Obviously, such a design requires a dedicated detector set-up. Dependent on the type of substrate used (see below) and/or size of the deposited spots, often special optics, such as a (diffuse) reflectance unit, a beam condensor or an IR microscope, are used to scan the deposited compounds.

Basically three types of substrates and corresponding IR modes are used in solvent-elimination LC/IR: powder substrates for diffuse reflectance Fourier transform infrared (DRIFT) detection; metallic mirrors for reflection/absorption (R/A) spectrometry; and IR-transparent windows for transmission measurements. In early solvent-elimination LC/IR designs DRIFT detection of analytes on potassium chloride (KCl) powder was used, but today other, more convenient, detection modes are preferred. DRIFT as such is one of the most sensitive IR modes and sub-microgram identification limits can be achieved when the residual solvent is evaporated quickly from the powder. If the eluent is not highly volatile, it can draw analyte away from the KCl powder surface into the substrate. This will limit the sensitivity, because the effective penetration depth of a DRIFT measurement is not more than 100 µm. To overcome this problem, diffuse transmittance spectrometry has been applied instead of DRIFT, using a layer of KCl powder on an IR-transparent substrate.\(^{37}\)

The main limitations of DRIFT detection in LC/IR, show up during application. Reproducibility is hard to control since factors such as sample homogeneity, sample load and compactness of the powder layer significantly influence the DRIFT analysis. Reorientation of the DRIFT...
matrix as a result of sample deposition may lead to a poor background compensation. Careful filling of cups or trays with the powder substrate is very time-consuming and has to be repeated for every analysis. Finally, common substrates such as KCl powder cannot be used in combination with aqueous eluents. In view of the overriding importance of RPLC, this is a very serious restriction. Some authors have used diamond powder as a water-resistant DRIFT substrate, but it is expensive (and thus not disposable) and not easy to clean.

Front-surface aluminum mirrors, which are suitable for R/A detection, are compatible with aqueous eluents and are relatively easy to handle. Compound deposition on this type of substrate requires efficient solvent-elimination interfaces because residual solvent will easily spread over the hard and smooth reflective surface. The band intensities in the R/A spectroscopy are largely governed by a double-pass transmittance mechanism, so that spectral data analogous to transmission data are obtained. Some useful results of solvent-elimination LC/IR using mirrors have been reported, although several authors\(^{38-40}\) have reported evidence of band asymmetry and spectral distortions. Aspects such as specular and diffuse reflection from the analyte, thickness and microcrystallinity of the spot, and optical characteristics of the substrate affect the shape and intensity of R/A spectra obtained from analytes on aluminum mirrors. The use of an IR-transparent germanium disc with a reflective backing has been proposed in order to reduce spectral distortions. This type of disc is used in the commercially available LC-Transform™ LC/IR interfaces.\(^{10}\) The cleaning of aluminum mirrors in between analyses is quite delicate: the thin metal layer is fragile and can be damaged easily by rubbing.

Most favorable results in solvent-elimination LC/IR are obtained with IR-transparent deposition substrates that allow straightforward transmission measurements. So far mainly KBr and ZnSe windows have been applied in experimental LC/IR set-ups. These substrates have a hard and smooth surface and, therefore, eluent elimination has to be fast to achieve proper depositions. ZnSe is a water-resistant, inert material, while KBr usually cannot be used in combination with RPLC. Deposited compounds on ZnSe can be removed simply, with water or alcohol, so that one window can be used repeatedly. With ZnSe, good-quality IR spectra with symmetrical band profiles can be recorded from deposited spots. When the size of the sample spots is small and microscopic optics are used for measurement, the sensitivity of ZnSe transmission measurements is higher than the sensitivity of DRIFT measurements.\(^{40}\) ZnSe windows also cause fewer spectral artifacts than mirror substrates for R/A detection.\(^{39}\) Many LC/IR studies demonstrated that spectra obtained using ZnSe, closely resemble conventional KBr-disk transmission spectra. Consequently, existing spectral libraries and search programs can be used for identification purposes, which is very important for the acceptance of IR as a valuable detection technique.

The quality and appearance of spectra obtained with solvent-elimination LC/IR will be influenced by the morphology of the deposited analytes. The morphology will depend primarily on parameters such as eluent composition, evaporation rate, temperature and nature of the substrate and the analytes. During solvent elimination some compounds will form nice crystals while others will deposit as an amorphous layer. Also, some analytes will deposit as a smooth film, whereas others may form irregular clusters. When the spot thickness exceeds a certain level, the effect of light scattering may become apparent. A compound may also exhibit polymorphism so that mutually (slightly) different spectra can be obtained for the same compound. In general, IR detection of deposited compounds on IR-transparent substrates does not pose serious problems. However, analyte morphology should always be taken into consideration during spectral interpretation.

In solvent-elimination LC/IR the identification limits usually improve when the width of the analyte spots is decreased. A prerequisite for this gain is the use of the appropriate detector and sampling optics. Optimum solvent-elimination interfaces can produce analyte spots with a width as small as 100–300 µm. For these deposits, the focus of a conventional beam condenser is too large and the use of an IR microscope is indicated. Frequently, the sensitivity enhancement is rationalized by considering the relatively increased spot thickness only (Beer’s law!), but this approach is too simple. From more complete S/N considerations it follows that the good sensitivity of IR microscopic detection essentially results from the low noise level of the IR detectors in IR microscopes.\(^{4}\) In other words, to achieve the most sensitive IR detection in LC, the width of the analyte deposits should have the same dimensions as the microscope detector area (typically, 100–200 µm). Of course, as with any IR experiment, the S/N ratio also can be improved by increasing the measurement time (signal averaging). As outlined in section 2.2, this advantage can be exploited to its full extent in solvent-elimination LC/IR, although at the cost of an increased time of analysis.

4.2 Early Interfaces

The solvent-elimination systems that were developed in an early stage, generally used KCl-powder substrates for DRIFT detection or flat KBr windows for transmission detection. The first working interface for the coupling of NPLC and IR was designed by Kuehl and Griffiths.\(^{3,41}\)
The organic eluent was led through a heated concentrator tube and dropped into a series of cups filled with KCl powder suited for DRIFT analysis. A carousel rotated the cups into the IR spectrometer where identifiable spectra could be recorded for sub-microgram amounts of analyte. In order to allow for RPLC separations, the aqueous effluent was first on-line extracted with dichloromethane which, after continuous phase separation, was directed through the concentrator to the KCl cups.\footnote{42} For extracted compounds good-quality spectra were obtained. The carousel–DRIFT method was also adopted for narrow-bore NPLC (use of 1-mm i.d. column) by reducing the size of the KCl cups and by omitting the concentrator tube.\footnote{43} Using a similar set-up, Kalasinsky et al.\footnote{44,45} coupled both narrow-bore NPLC and RPLC with DRIFT. The KCl-powder substrate was held either in a “train” of compartments or in a continuous trough. Aqueous eluents could be used by on-line conversion of the water into methanol and acetone via a post-column reaction with 2,2-dimethoxypropane (DMP). The identification limits of these systems were 1–3 µg, typically.

The early DRIFT-based systems for the first time demonstrated that solvent-elimination LC/IR can provide (much) better sensitivity and spectral quality than flow-cell based LC/IR. However, the systems were mechanically complex and tedious to work with, and DRIFT detection appeared to be strongly affected by small disturbances of the KCl-powder surface and by the presence of (residual) water.

Jinno et al.\footnote{46–47} proposed the use of micro-LC columns (i.d., 0.3 mm) in solvent-elimination LC/IR in order to alleviate the problem of the evaporation of large eluent volumes. The effluent (5 µL min\(^{-1}\)) from either a GPC or an NPLC was led directly to a moving KBr plate which was covered by a stream of heated nitrogen. Subsequently, the plate with the deposited track was scanned by IR transmission spectroscopy using a 3 x beam condensor. The potential of the approach (termed “buffer-memory” technique) was illustrated by the analysis of a mixture of dithiocarbamate metal complexes by three spectroscopic techniques.\footnote{47} In a modified set-up the linearly moving KBr plate was replaced by a rotating KBr disk which, after the chromatographic run was finished, was transferred to a special rotation module in the IR spectrometer.\footnote{48} In order to permit the use of RPLC, a SS wire net (WN) was used instead of an KBr window.\footnote{49} IR transmission measurements were possible because after deposition and drying the analytes were partly suspended in the metal meshes.

The “buffer-memory” technique demonstrated the usefulness of the storage of a continuous chromatogram on a flat substrate. Besides, it was considerably simpler than the DRIFT methods. However, at least several micrograms of analyte were needed for a positive IR identification. These amounts often exceeded the sample capacity of the micro-columns and required unrealistically high concentrations to be injected.

### 4.3 Spray-type Interfaces

When using the “buffer-memory” technique for compound deposition on flat substrates, it is not possible to eliminate organic or aqueous eluents at flow rates higher than about 5 µL min\(^{-1}\) without spreading the compounds over a large area of the substrate surface. To achieve a more viable coupling of LC and IR, the use of interfaces with enhanced evaporation power is essential. The solvent-elimination interfaces developed in the last decade all use some kind of spraying to induce rapid eluent evaporation. Heat, gas, electric potential and/or ultrasonic vibrations are used to break up the LC eluent stream into small droplets. Some designs incorporate existing (commercial) equipment, while others have been built from scratch.

In the thermospray (TSP) interface, originally developed for liquid chromatography/mass spectrometry (LC/MS), a directly heated tube evaporates part of the column effluent to an expanding vapor causing nebulization of the remaining effluent. As a result, a mist of desolvating droplets emerges from the tube. In the TSP-based LC/IR systems, nebulization is performed at atmospheric pressure and the spray is directed towards a deposition substrate. Eluent flow rates of up to 1 mL min\(^{-1}\) can be handled. Griffiths and Conroy\footnote{50} reported preliminary results on the use of TSP for LC/IR, but the first really working interface was introduced by Jansen.\footnote{51} With a home-made TSP, the LC effluent was sprayed on a SS IR-reflective tape which moved through an optical accessory in the IR spectrometer (Figure 7). Most of the eluent was eliminated directly by the TSP and residual solvent was evaporated off the tape by heating. The immobilized chromatogram was monitored.

**Figure 7** Schematic of TSP–moving belt interface for LC/IR; 1, moving SS tape; 2, TSP; 3, heater; 4, IR reflectance cell mounted in the IR spectrometer.
continuously and full IR spectra were recorded. Several simple polymer samples (20–80 µg injected) were analyzed by GPC/IR using an organic eluent at a flow rate of 0.5–1 mL min\(^{-1}\), but some low-molecular-weight monomers were too volatile to be deposited. The characterization of two Irganox-type polymer additives (100 µg each), which were separated by RPLC using an eluent (0.5 mL min\(^{-1}\)) with 30 vol% water, was also shown. Robertson et al.\(^{(52)}\) further optimized the TSP–moving belt interface by studying the effect of the TSP temperature and distance to the substrate. The system was used for the analysis of amino acids, saccharides, carboxylic acids, antioxidants and polymers,\(^{(53,54)}\) and analyte identification could be achieved down to concentrations of 50 µg mL\(^{-1}\) or about 2.5 µg injected.

The main advantage of the TSP-based systems is that relatively high flow rates (0.5–1 mL min\(^{-1}\)) of both organic and aqueous eluents can be handled and conventional-size LC can thus be used. Furthermore, spectral data are acquired during the run, which gives the IR detector an essentially on-line character. On the other hand, the high temperature of the TSP may induce analyte losses by evaporation or thermal degradation and the analyte spots on the moving tape are still quite large which results in a moderate IR sensitivity.

The particle beam (PB) interface was modified for LC/IR by de Haseth et al.\(^{(55,56)}\) and Wood.\(^{(57)}\) In this interface the LC eluent is nebulized by helium and directed into a desolvation chamber where most of the liquid is vaporized. The mixture of gas, vapor and condensed analyte molecules (i.e., particles) is accelerated into the momentum separator where the analytes travel straight through the skimmer cone, while the gas and vapour are pumped away. For IR detection an IR-transparent substrate is placed in the particle-beam path to collect the analytes of interest (Figure 8) and after deposition, the substrate is transferred to the IR spectrometer for analysis. Until now stationary substrates have been used in liquid chromatography/particle beam/infrared (LC/PB/IR), that is, no complete chromatograms, only fractions, were analyzed. The particle beam/infrared (PB/IR) interface can effect the elimination of aqueous eluents at flow rates of up to 0.3 mL min\(^{-1}\) as was demonstrated by the analysis of erythrosin B and \(p\)-nitroaniline (50 µg each) by RPLC/IR.\(^{(58)}\) Since the PB interface has strong eluent-elimination capacities, it was believed that interference caused by buffers might be small.\(^{(58)}\) The interface indeed appeared to be able to process a 0.3 mL min\(^{-1}\) flow of buffered eluent, but the buffer salts were never completely eliminated. Best results were obtained with eluents buffered with ammonium acetate, although buffer bands were clearly present in the IR spectra recorded from microgram amounts of analyte. When phthalate or phosphate buffers were used, the analyte spectra were completely dominated by absorption bands of the buffer salts. Spectral subtraction procedures could be used to recover spectra from 130-µg depositions but were unsuccessful at the 13-µg level. PB/IR has been used as a tool for the determination of protein structures.\(^{(59–61)}\) For \(\beta\)-lactoglobulin and lysozyme it was shown that their structural integrity is maintained during the PB desolvation process and the subsequent deposition on the substrate. In addition, lysozyme appeared to retain its biological activity. The sample loads in these experiments generally were quite high (5–500 µg).

The PB interface can effectively remove both organic and aqueous solvents. However, relevant applications in LC/IR would still require the construction of a device that allows the continuous deposition of a complete chromatogram on a moving substrate. The PB/IR analysis of compounds at the nanogram level has been demonstrated.\(^{(55)}\) The interface \(\alpha\) and \(\beta\) phases were used to recover spectra from 130-µg depositions but were unsuccessful at the 13-µg level. PB/IR has been used as a tool for the determination of protein structures.\(^{(59–61)}\) For \(\beta\)-lactoglobulin and lysozyme it was shown that their structural integrity is maintained during the PB desolvation process and the subsequent deposition on the substrate. In addition, lysozyme appeared to retain its biological activity. The sample loads in these experiments generally were quite high (5–500 µg).

The potential of electrospray (ESP) nebulization for micro-LC/IR was studied by Raynor and co-workers.\(^{(62)}\) A high electrical potential is used to form a spray of charged droplets at the end of a capillary filled with flowing liquid. As a result of charge density, the initial droplets break up into smaller droplets which
facilitate solvent evaporation. Use of low flow rates (typically 1–20 µL min⁻¹) is indicated in order to obtain a stable ESP. The ESP is formed under atmospheric conditions and a sheath flow of nitrogen gas is applied to enhance eluent evaporation (Figure 9). The ESP interface was used to deposit the effluent from a micro-RPLC column onto a ZnSe plate. After LC separation, 20-ng amounts of caffeine and barbitual could be analyzed successfully using pneumatic nebulization, while removal of aqueous solvents is possible when the nebulizer gas is heated. Pneumatic nebulizers have been used in several solvent-elimination LC/IR designs, among which are the most successful so far. One of the first nebulizer-based LC/IR methods involved the continuous spraying of the effluent from a narrow-bore NPLC column on a rotating IR-reflective disk (Figure 10). The effluent was mixed with nitrogen gas to form a fine spray and the immobilized chromatogram was analyzed by rotating the disk through a 3 × condensed IR beam while recording R/A spectra. The system was tested with polycyclic aromatic compounds (200–800 ng each) which were separated using hexane–dichloromethane as eluent (30 µL min⁻¹). Good-intensity spectra were obtained, although some spectral deviations were observed. This pneumatic nebulizer design was improved to accomplish elimination of aqueous solvents. A heated nitrogen flow served as an evaporation-enhancing and spray-focusing sheath gas.
Eluents containing up to 55% water could be handled at 30 µL min⁻¹ and a number of isomeric naphthalenediols (500 ng each) were separated and identified. Again the recorded R/A spectra showed anomalies. These spectral problems could be partially solved by using an IR-transparent germanium disk with a rear surface of aluminum as substrate. This pneumatic nebulizer LC/IR design is commercialized by Lab Connections. The instrument consists of a sample-collection module and an optics module for R/A analysis. So far the commercial interface has been applied mainly in the field of GPC/IR.

A simple but effective concentric flow nebulizer (CFN) for the coupling of narrow-bore LC and IR spectrometry was constructed by Lange et al. The interface consists of two concentric fused-silica capillaries. The LC column effluent is led through the inner capillary and heated helium gas through the outer capillary (Figure 11a). The hot gas facilitates the evaporation of the solvent and the focusing of the spray emerging from the inner tube. To enhance the elimination of aqueous eluents, the CFN and the ZnSe substrate were placed in a vacuum chamber (Figure 11b). IR microscopy was used for optimum detection. The CFN can handle eluents with up to 100% water at a flow-rate of 50 µL min⁻¹ and identifiable spectra of analytes can be recorded down to the low-nanogram range. The CFN was also installed in an evacuated compartment which included the IR-microscopic optics and a motor to translate the ZnSe window. With this system, an RPLC effluent (50 µL min⁻¹) could be continuously deposited on the moving substrate. After immobilization of the chromatogram, spectral data could be collected without the need to transport the substrate from the Chromatograph™ to the IR spectrometer. To further improve the on-line character of the system, a modified CFN was installed on the optical bench of a Tracer (Biorad, Düsseldorf, Germany) gas chromatography–IR interface which allows spectral acquisition in real time. So far, only some preliminary results with this on-line LC/IR system have been reported. Unfortunately, proper analyte spectra cannot be obtained with the CFN/IR system when using nonvolatile buffers, because of strong co-deposition of buffer salts. However, if sufficient vacuum pump capacity is applied, a 1 mM ammonium acetate buffer can be completely eliminated, although higher ammonium acetate concentrations cause interference.

Somsen et al. proposed a spray-jet interface for the coupling of narrow-bore RPLC and IR spectrometry. In this interface a heated nitrogen flow provides pneumatic nebulization of the column effluent (20 µL min⁻¹) which is led through a SS needle that protrudes through a spray nozzle (Figure 12). With ZnSe as substrate and IR microscopy for detection, identification limits in the 10–20-ng range were achieved for quinones and polycyclic hydrocarbons. The narrow-bore RPLC/IR system was used for the impurity profiling of a steroids, for the isomer-specific characterization of chlorinated pyrenes, and for the identification of additives in polymer samples. Furthermore, the suitability of the interface for GPC/IR was demonstrated by analyzing polystyrene oligomers. When RPLC is applied, the spray-jet LC/IR system is limited with regard to the LC flow rate, the water percentage of the eluent and the handling of buffered eluents. In order to take away these limitations, a post-column LLE module (phase segmentor, extraction coil and phase separator), was inserted on-line and...
the organic phase, carrying the extracted analytes, was sent to the evaporation interface. The resulting liquid chromatography/liquid–liquid extraction/infrared (LC/LLE/IR) system can handle eluents with high water percentages (20–100 vol%) at flow rates up to 0.2 mL min\(^{-1}\) and provides identification of compounds at the sub-milligram per liter level. Since the salts are not extracted, nonvolatile buffers can be used without causing interference. The detectability of the analytes was further improved by incorporation of on-line SPE for analyte enrichment (Figure 13). With such a system, triazine herbicides, including several isomers, could be identified at the low-microgram per liter level in river water (Figure 14).

In an alternative approach to improve the compatibility of the spray-jet interface with RPLC, the eluent flow rate was reduced to 2 µL min\(^{-1}\). To obtain a useful spray, a make-up liquid (20 µL min\(^{-1}\) of methanol) was added to the micro-LC effluent. As a consequence, the performance of the interface became independent of the water content of the eluent, so that gradient elution was possible. A micro-precolumn for on-line trace enrichment was applied to improve detection limits. With a 40-µL sample volume, good-quality IR chromatograms and analyte spectra were recorded at the low-milligram per liter level.

In an ultrasonic nebulizer a spray is formed by depositing the LC effluent on a transducer that is vibrating at ultrasonic frequencies. For LC/IR purposes, the spray is directed towards a substrate by a carrier gas. Castles et al. used ultrasonic nebulization for the deposition of compounds separated by narrow-bore RPLC on a diamond-powder substrate suitable for DRIFT detection. Spectra of satisfactory quality were obtained.
Figure 14 SPE and LC/LLE/IR chromatograms of river Meuse water samples spiked with five triazines: (a) 20 mL (30 µg L⁻¹), (b) 50 mL (6 µg L⁻¹) and (c) 100 mL (2 µg L⁻¹). IR spectra of peaks 1, 3 and 5. Chromatogram representation, (a) Gram–Schmidt or (b and c) spectral window (1650–1500 cm⁻¹). for injections of 3 µg of analyte. In some instances, the complete and direct evaporation of the eluent by the ultrasonic nebulizer was not achieved because the vibrating surface was not uniformly effective and occasionally large droplets were formed which wetted the diamond powder. Dekmezian and Morioka developed an interface for high-temperature GPC/IR which involved an ultrasonic nebulizer. The nebulizer was placed in a vacuum chamber and sprayed the column effluent on a set of heated KBr discs, which were subsequently analyzed by IR transmission spectrometry. The system was applied to the determination of compositional changes of ethylene–propylene rubbers. An interface comprising an ultrasonic nebulizer in a vacuum chamber is used by Lab Connections in their LC-Transform™ 300 Series. This commercial device sprays
the chromatographic effluent on a rotating germanium collection disk suited for R/A analysis (see above). The system was used for the quantitative analysis of copolymers by GPC/IR and for steroid analysis by RPLC/IR.

5 STATE OF THE ART

In the contemporary practice of LC/IR both flow-cell and solvent-elimination approaches are applied. Since the flow-cell procedure cannot get around the detection limitations imposed by the LC eluent, it has developed into a special-purpose method with restricted applicability. The IR absorptions of any solvent invariably take up parts of the mid-IR spectral region and, therefore, the main power of IR spectroscopy, i.e. the reliable identification of compounds, cannot be fully exploited in flow-cell IR detection. Nevertheless, making use of the spectral windows of the eluent, flow-cell IR spectroscopy can serve as a moderately sensitive, compound-specific detection technique. Occasionally, it is used as a universal, fast and low-cost method to obtain quantitative and structural information on major constituents of samples. Various types of flow cells are commercially available, and the experimental set-up and practice of flow-cell LC/IR is relatively simple and well-suited for routine applications.

When the objective of IR detection in LC is the unambiguous identification of (low-level) constituents of mixtures, coupling via solvent elimination should be the approach of choice. Solvent elimination procedures offer the possibility

- to record spectra over the entire mid-IR region without interference from the eluent;
- to perform signal averaging in order to improve the S/N of the spectra; and
- to contain a relatively large part of the chromatographic peak within the IR beam.

As a result, the solvent-elimination approach provides a set-up which features increased sensitivity and enhanced spectral quality, two important conditions for effective analyte identification. The most recent commercial LC/IR systems which are presently available,\(^\text{10,11}\) are solvent-elimination devices. Interestingly, also in gas chromatography and supercritical-fluid chromatography analyte-deposition-based IR detection has proven to be more sensitive and versatile than flow-cell-based techniques. On the other hand, one should realize that the vibrational information obtained after solvent elimination is different from the vibrational information obtained with flow-cell detection (condensed-phase spectra against solution-phase spectra). Recently, this difference was used to determine subtle molecular features of drug metabolites which were analyzed by both flow-cell and solvent-elimination LC/IR.\(^\text{82}\)

Today, the vast majority of LC separations is carried out by means of RPLC and, not surprisingly, research in the field of LC/IR has concentrated on the development of interfaces that are suitable for the elimination of aqueous eluents. Table 2 summarizes the characteristics of the various solvent-elimination reversed-phase liquid chromatography/Fourier transform infrared (RPLC/FTIR) systems which have been developed during the last years. The systems based on TSP, PB and ultrasonic nebulization

\(^b\) Typical values.
can handle relatively high flows of aqueous eluents and allow the use of conventional-size LC, which evidently is an advantage. However, these systems often exhibit moderate, or even unfavorable identification limits and, therefore, their analytical applicability is limited. Until now, the most favorable results have been obtained with pneumatic nebulizers which essentially represent the state of the art in solvent-elimination LC/IR.

The pneumatic interfaces combine rapid solvent elimination with a relatively narrow spray. This implies that analytes can be deposited, for example on ZnSe, in a narrow track of spots and IR microscopy can be applied effectively to achieve mass sensitivities in the low-nanogram range. Bearing in mind that often only part of the injected amount of analyte is actually analyzed, this means that the mass detectability of these LC/IR systems approaches a level close to the minimum that can be identified by IR spectroscopy. The systems based on pneumatic nebulization are limited with regard to flow rate (2–50 \( \mu \)L min\(^{-1} \)) and water percentage of the eluent. The tolerable water content of the eluent depends on the flow rate. Flow rates of 2–5 \( \mu \)L min\(^{-1} \) of even pure water can be eliminated, but for 20–50 \( \mu \)L min\(^{-1} \) flows of aqueous eluents, enhancement of the solvent evaporation efficiency is required, for example by mixing the effluent with nitrogen gas\(^{(38)} \) or by placing both the nebulizer and the deposition substrate inside a vacuum chamber.\(^{(38)} \) The tedious evaporation of water can also be circumvented by applying on-line LLE of the aqueous effluent with an organic solvent. Such a system allows much higher flow rates (0.2 mL min\(^{-1} \)) and percentages of water (up to 100 vol\%).\(^{(72, 76)} \) Of course, the required LLE module adds to the complexity of the system and the analytes must have a sufficiently high extraction efficiency. Solvent-elimination RPLC/IR with gradient elution poses the problem of the efficient evaporation of an eluent with a changing water content. One solution involves the increase of the temperature of the nebulization gas during the gradient run,\(^{(38)} \) another the addition of excess methanol to a micro-LC effluent in order to mask the changes in its water content.\(^{(77)} \)

The injection volumes that can be handled with micro- and narrow-bore LC columns, are at most 1–2 \( \mu \)L. The identification limits in terms of concentration units of the pneumatic nebulizer-based systems therefore are in the low-milligram per liter range, which is sufficient for a number of analytical applications.\(^{(72–74)} \) By using the LLE-pneumatic nebulizer combination, the detectability can be improved to sub-milligram per liter levels because larger LC columns – and, thus, increased injection volumes – can be used. With an adequate trace-enrichment procedure such as on-line SPE, the LC/IR detection limits can be further improved down to the low-microgram per liter level.\(^{(76)} \) The use of buffered eluents is generally avoided in solvent-elimination LC/IR, since buffer salts may seriously affect the deposition and detection of the analytes. With pneumatic nebulizers even volatile buffer salts are rarely completely eliminated. In fact, until now the LLE-pneumatic nebulizer combination is the only described LC/IR system which allows the use of nonvolatile buffer salts without introducing interfacing disturbances and/or spectral interference.\(^{(75, 76)} \)

Effective solvent elimination by the pneumatic nebulizers allows the use of deposition substrates with a hard and smooth surface such as ZnSe windows. With these substrates interference- and distortion-free transmission spectra are obtained which can be readily compared with conventional KBr-disk IR spectra. This implies that libraries of condensed-phase reference spectra can be used for spectral recognition and identification. Compounds of various nature such as quinones, steroids, drugs, polymer additives and herbicides have been analyzed successfully by pneumatic-nebulization-based LC/IR. The interfaces can handle most types of analytes, although too volatile compounds will be evaporated by the nebulizer gas and therefore will not be deposited on the substrate. Thermal degradation of analytes is commonly not observed during pneumatic nebulization, despite the fact that the nebulizer gas is heated to rather high temperatures (70–180 °C). Probably, due to the rapid evaporation of the solvent, the spray droplets are cooled considerably.

6 PERSPECTIVE AND FUTURE DEVELOPMENTS

In the last fifteen years, LC/IR has emerged as a potentially powerful tool for the specific detection of major components (flow-cell approach) or for the identification of (minor) constituents of complex mixtures (solvent-elimination approach). With respect to common LC detection techniques such as UV/VIS absorption detection, the sensitivity of flow-cell IR detection is rather poor and its merits therefore mainly lie in the ability to quantitatively monitor absorptions that are specific for the analyte or for a certain functional group. Since the limitations of flow-cell LC/IR are inherent in the technique, no vast improvements can be anticipated in the future. Some gain in performance may be achieved by optimization of the flow-cell design and use of advanced FTIR spectrometers, but these improvements will be modest and not essentially change the applicability of flow-cell IR detection. Employment of chemometrical techniques, however, may be useful particularly when the signal or spectrum is the result of the absorbance of two or more substances.

The usefulness of solvent-elimination LC/IR to provide structural information and/or identification of unknowns...
has been demonstrated convincingly since 1990. Unfortunately, the development of coupling techniques proceeded, and still proceeds, quite slowly and until now most interfaces have been used only by their designers. Nevertheless, the difficulty of solvent-elimination LC/IR, i.e., simultaneous eluent evaporation and analyte deposition, seems to be a technical rather than a fundamental problem. In other words, the development of an overall effective and routinely applicable interface probably is a matter of time, effort and technological innovations. Of course, solvent-elimination LC/IR has to compete with other identification techniques of which today on-line LC/MS undoubtedly is one of the most important. Quite a number of LC/MS interfaces have been developed and commercialized, but still each interface has its specific limitations. Furthermore, MS techniques cannot discriminate between isomers. Hence, even with adequate LC/MS techniques available, there is a need for alternative and complementary detection techniques which independently confirm MS-based identifications and differentiate between structurally highly similar compounds. A recent study demonstrated that LC/IR can make a viable contribution to identification analysis in a research setting that includes MS and NMR. Prerequisite for the successful implementation of IR detection was a good understanding of the relative strengths and weaknesses of each technique, and the integration of analysis in the total research program.

In order to enhance the acceptance of solvent-elimination LC/IR, several items of interest should be considered. The practicality of the technique for real-life samples should be demonstrated more extensively. The applications described so far indicate that LC/IR can indeed be used for the characterization and unambiguous identification of target and unknown compounds. LC/IR is particularly useful for the distinction of isomeric compounds which cannot be distinguished by LC/MS. Another item of attention is the development and use of appropriate on-line sample-treatment procedures to improve analyte detectability. Despite the low-nanogram identification limits, the detectability in concentration units of even the best LC/IR systems will not be sufficient to meet current demands in bio- and environmental analysis. On-line SPE can improve the concentration detectability by one or two orders of magnitude. Obviously, such an improvement is unlikely to be obtained by optimization of interfacing and/or IR detection only. The first studies indicating this advantage in both flow-cell and solvent-elimination IR-detection have already been reported.

Concerning the viability of solvent-elimination LC/IR, the availability and use of commercial interfaces also is essential. The LC-Transform interface (Lab Connections) has been available now for several years, but unfortunately few applications have been reported. Because this solvent-elimination system uses a mirror substrate and standard IR equipment, both the IR sensitivity and spectral quality are limited. In a more viable approach an IR-transparent substrate should be used together with microscopic IR detection. Such a configuration is used by the Infrared Chromatograph interface (Bourne Scientific). In this commercial and automated design the LC column effluent is deposited on a moving ZnSe window which instantaneously passes through the focused beam of the IR spectrometer allowing spectra and IR chromatograms to be recorded in real time. The placement of the chromatograms on the substrate is controlled by computer which also keeps a record of the position of deposited compounds. The IR Chromatograph seems promising but, as it has been introduced only recently, it is still too early to assess its merits. The handling of the obtained spectral data also is a matter of concern in solvent-elimination LC/IR. The identification of analytes on the basis of their IR spectra often is a difficult operation. Therefore, the automated retrieval of spectra in reference collections, and the computerization of spectral interpretation are important. Several such procedures have already been introduced in the vibrational-spectroscopic field and high priority should be given to their implementation in the separation field.

Finally, it should be noted that the solvent-elimination approach in LC is not restricted to IR detection but can, in principle, be applied to any spectrometric technique which requires the compounds of interest to be present as deposits. An example of such an analyte-deposition-based detection technique is matrix-assisted laser desorption/ionization (MALDI) MS. From a technical viewpoint the collector systems developed for the coupling of LC or capillary electrophoresis with MALDI/MS show a strong similarity with solvent-elimination LC/IR systems.

The essential features of an infrared (IR) microscope accessory include:

1. reflective optics for focusing, collecting, and imaging transmitted or reflected IR radiation from the sample onto a detector,
2. one or more variable apertures located in an image plane of the sample which serve to define the area to be recorded, and
3. a visible light path which is parfocal and collinear with the IR light path so that the sample can be viewed and positioned.

The accessory is coupled to a Fourier transform IR (FTIR) spectrometer by a set of transfer optics from the interferometer into the microscope.

IR microspectroscopy provides the analyst with the capability to perform IR transmission, absorption-reflection, specular reflection, and diffuse reflection experiments on microscopic samples. Using special microscope objectives or accessories, attenuated total reflection (ATR) and grazing angle reflection experiments can be performed as well. IR microspectroscopy can also be used to map a sample’s heterogeneity using a motorized stage in conjunction with a standard mercury cadmium telluride (MCT) detector. Alternatively, spatial and spectral information can be collected simultaneously using a step-scan interferometer coupled with an IR microscope and a focal plane array (FPA) detector. In either case, the superior contrast attained by functional group imaging and the selectivity found in the mid-IR region has been shown to be a powerful analytical tool.

However, diffraction ultimately limits the quality of the spectral information obtained using the IR microscope, and its effects may include poor spatial resolution, a reduction in photometric accuracy, and unreliable band intensities. Furthermore, unwanted optical effects from microscopic samples can also affect the quality of the spectrum, and sample preparation techniques must often take into account a sample’s thickness, diameter, refractive index, and shape.

1 INTRODUCTION

1.1 History

IR microspectroscopy is the coupling of a microscope with an IR spectrometer for the purpose of obtaining spectra on microscopic samples. A mid-IR reflective microscope was first reported in 1949 at Oxford, England in H.W. Thompson’s laboratory, and, soon after, the first commercially available IR microscope accessory was manufactured by the Perkin-Elmer Corporation. (1,2)

Early investigators were interested in medical and biological applications and recorded spectra of single fibers, tissue sections, and blood smears. (3) But high-quality spectra were difficult to obtain on dispersive IR spectrometers.

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd
owing to the high energy losses of the microscope. Consequently, the technique remained little used until the development of FTIR spectrometers with their inherent throughput, multiplex, and frequency precision advantages. IR microspectroscopy consequently regained popularity, and a mid-IR microscope designed for the FTIR spectrometer was introduced at the 1983 Pittsburgh Conference and Exposition by Digilab Corporation. Two years later the first symposium on the “Design, Sample Handling, and Applications of Infrared Microscopes” was held at a meeting sponsored by the American Society for Testing and Materials (ASTM) Committee on Molecular Spectroscopy and the Federation of Analytical Chemistry and Spectroscopy Societies; nine papers presented there were written, peer-reviewed, and published.

1.2 Rationale
Not only does the IR microscope accessory provide the analyst with the capability to obtain IR spectra on extremely small samples, it is a versatile accessory which can be used for transmission, absorption-reflection, specular reflection, and diffuse reflection experiments. With special microscope objectives or accessories, attenuated total internal reflection and grazing angle reflection experiments can also be performed. Consequently, the technique allows for a wide variety of samples to be studied, and the reflection experiments, in general, offer ways to sample both microscopic and macroscopic samples with little or no preparation. Another important use of IR microspectroscopy is that the molecular heterogeneity of samples can be imaged and mapped.

However, IR microspectroscopy offers a number of challenges in regard to instrumental design and sampling. Diffraction ultimately limits the spatial resolution which can be obtained using the IR microscope, and unwanted optical effects from microscopic samples can affect the quality of the spectrum.

Finally, owing to the selectivity of molecular information which can be attained, the vast number of applications of IR microspectroscopy found in the literature have been in the mid-IR region. The review will therefore focus primarily on the instrumental methods of mid-IR microspectroscopy in the wavelength range from 2 to 20 µm, including how one minimizes the effects of diffraction, refraction, reflection, and absorption by sampling techniques or instrumental parameters. However, near-infrared (NIR) microspectroscopy is an emerging field with distinct advantages in regard to some sampling factors and instrumental design considerations, and these aspects will be addressed as well. For all the apparent advantages of NIR microspectroscopy which will be mentioned, the facts remain that both the inherent functional group contrast needed for NIR imaging and the selectivity which allows for material identification are highly limited. IR microspectroscopy in the mid-IR range is generally far superior and more widely applicable.

2 THEORETICAL CONSIDERATIONS IN INSTRUMENT DESIGN

2.1 Diffraction
Diffraction plays a major role in microspectroscopy when the sample size is on the order of the wavelength of light being used according to Rayleigh’s relationship described in Equation (1):

\[
D = \frac{1.22\lambda}{NA}
\]

where \( D \) is the diameter of the object and \( \lambda \) is the wavelength of light. \( NA \) is the numerical aperture which is a measure of the collection ability of an optical system.

The effects of diffraction are graphically illustrated in Figure 1 which shows the diffraction pattern, or Airy disk, which results when a 17 µm IR point source is imaged by an optical system with a NA of 0.58, a typical NA for an IR microscope objective. (17 µm is the longest wavelength in the mid-IR range detected by a narrow-band MCT detector.) Notice that the energy is not imaged to a point but appears as a succession of bright rings which contain some of the energy from the original source. For the experimental conditions described, there will be 85% of the energy of the point source within the first bright ring. The remaining energy is contained within the second and third bright rings which are smaller in diameter.

Figure 1 Graphical representation of an Airy disk for a 17 µm point source focused by an optical system with a 0.58 NA. The dimensions given are the outer diameters of the bright rings.
the total original energy in the central spot, which is 36 µm in diameter as calculated by Equation (1). The rest is distributed among the remaining rings, and 5% of the energy still remains beyond the outer diameter of the fourth ring at 124 µm. Likewise, the IR radiation collected from a 17 µm diameter sample will result in a “blurring” of spectral information. The energy which reaches the detector will primarily contain information about the sample, but like the fringes of the Airy disk, radiation which is present outside areas defined by the aperture, called spurious energy, can also reach the detector. Studies show that using a 8 µm effective diameter aperture results in an actual sampling diameter of 48 µm, for example, while using a 24 µm aperture results in a sampling diameter of 56 µm. Diffraction effects can occur at either the high-contrast apertures located in the image plane(s) of the sample which are used to delineate the area or at the sample itself. Some of these effects can be addressed through sampling considerations and will be discussed in section 4.1.

First consider diffraction at the aperture. If an absorbing sample is nearby or adjacent to the sample under study, the spurious energy may result in absorption bands from the neighboring object “contaminating” the IR spectrum of the sample. The spatial resolution of the IR microscope is effectively decreased, and the two objects are not resolved. This is illustrated in Figure 2 which shows spectra of a cellulose acetate film obtained using a 8 mm × 240 mm aperture when the film completely fills the entire aperture (Figure 2a), when the edge of the film, out of view, is lined up with the edge of the aperture (Figure 2b), and after the edge of the film has been moved 40 µm away from the edge of aperture image (Figure 2c). Although there was no sample in the field of view defined by the aperture in the middle and bottom spectrum, spectral contamination is clearly present from the cellulose acetate even from 40 µm away, a situation with important implications for the analysis of multilayered polymer cross-sections.

If there is only a nearby hole, that is if the free-standing particle is well removed from any other sample, the stray light reaching the detector may result in an offset of zero percent transmission. The photometric accuracy is decreased, and quantitative measurements are affected.

One way to minimize the above diffraction effects is to use dual remote (confocal) aperturing where an aperture is placed in an image plane located both before and after the sample. For example, Figure 3 shows the IR spectra of a hair fiber collected with a single aperture placed before the sample, A, a single aperture placed after the sample, B, and with both apertures in place, C. (Reproduced by permission of Marcel Dekker, Inc. from J.E. Katon, A.J. Sommer, P.L. Lang, Appl. Spectrosc. Rev., 25, 173–211 (1989–1990).)
transmission spectrum obtained on a hair fiber collected with a single aperture (A and B) and with confocal apertures (C). Although the thickness of the fiber is such that the N–H stretching (3300 cm\(^{-1}\)) and the amide I and II (1650, 1550 cm\(^{-1}\)) absorptions are totally absorbing, a marked offset from zero transmission is observed for single aperture systems, while an improvement is noted for the confocal configuration.\(^7\)

It is important to note that while the theoretical spatial resolution using standard mid-IR microscope accessories is estimated at 34 \(\mu m\) using the previous criteria (17 \(\mu m = \lambda; 0.58 = NA\)), microspectroscopy in the near-infrared region, from 1 \(\mu m\) to 4 \(\mu m\), offers the potential for higher spatial resolution in accordance with Rayleigh’s criterion.

### 2.2 Numerical Aperture

Another variable in IR microspectroscopy which may be altered to our benefit is the NA. NA, is defined by Equation (2):

\[
NA = n_1 \sin \theta
\]  

(2)

where \(n_1\) is the refractive index of the medium and \(\theta\), is the half angle of collection.\(^{13}\) Figure 4 illustrates the how NA increases with collection angle.

Increasing the NA of the focusing lens and collecting objective will decrease the beam diameter as well as the distance needed to spatially resolve two closely spaced samples as Equation (1) predicts. It also increases the throughput, \(\Theta\), which is the product of the solid angle subtended by the objective and the area of the focused beam, \(A\). According to Messerschmidt\(^{13}\) the throughput is related to NA by Equation (3):

\[
\Theta = 2\pi [1 - (1 - (NA)^2)^{1/2}]A
\]  

(3)

Therefore one could design a microscope of high NA which would allow the use of dual aperturing to reject stray light while at the same time keep an adequate energy signal. Equation (3) predicts that for a system of 0.50 NA there is about five times more signal than for a 0.25 NA system.\(^{13}\) In addition, Messerschmidt has shown that the 95% confidence level for the spurious energy rejection occurs at a two-wavelength-wide slit width for a dual aperture system with a 0.50 NA versus at a four-wavelength-wide slit for a system with a 0.25 NA. Therefore, a dual-masked system of 0.50 NA can analyze samples two times smaller than a single-masked system of 0.25 NA with an equivalent level of spurious energy rejection and with an increase in signal by a factor of five.

As the NA of the lens increases, on the other hand, the working distance decreases.\(^{13}\) An adequate working distance is necessary for mounting cells and special stages and is therefore an important consideration in transmission experiments. For example, a 0.65 NA lens with 32 \(\times\) magnification has an 8 mm working distance, while a 0.58 NA lens with 15 \(\times\) magnification has a 15 mm working distance.\(^{16}\) In addition, as NA increases, so do spherical aberrations which effectively limit the flatness of fields for wide-area imaging.\(^{15}\) In other words, rays further from the optical axis are brought to a focus at a location nearer to the lens than those rays closer to the optical axis.

In regard to NIR microspectroscopy, a significant NA advantage can be achieved since refracting (glass) objectives can be employed. Refracting objectives, in comparison to reflective objectives which must be used in the mid-IR, can have higher NA. The use of higher NA objectives can result in an increase in both spatial resolution and throughput as described in Equations (1) and (3) respectively.\(^{15}\)

### 2.3 Signal-to-noise Ratio

Griffiths and de Haseth state that the largest source of noise in IR spectrometry is detector noise.\(^5\) Furthermore, the optimum performance is found when the optics are throughput-matched, a condition which exists when the detector is exactly filled by the image of the source.\(^5\) However, in regard to IR microspectroscopy, since the sample is brought into focus and defined by a variable aperture(s), the size of the image at the detector is dependent upon the sample size. Therefore microscope accessories are not designed for the system to be throughput-matched, for in doing so it would be ideal for one specimen size only.

It is customary for microscopes to be designed, aligned, and tested with a 100 \(\mu m\) diameter circular pinhole as the sample. If the optics provide 1:1 imaging from the sample to the detector, then a 100 \(\mu m\) diameter image will underfill a 250 \(\mu m\) by 250 \(\mu m\) area detector. Under these conditions, a 100% transmittance line at 2200 to 2100 cm\(^{-1}\) typically produces a signal-to-noise ratio (S/N) of 4000:1 or greater for a 2 minute collection time using

![Figure 4 The relationship of NA to collection angle.](image-url)
4 cm\(^{-1}\) spectral resolution, measuring peak-to-peak noise, and with a narrow or medium band MCT detector.

3 THE INFRARED MICROSCOPE

Figure 5 shows the essential features of the standard IR microscope. They include one or more variable apertures located in the image plane of the sample which serve to define the area to be recorded and reflective optics for focusing, collecting, and imaging transmitted or reflected IR radiation from the sample onto a detector. The microscope must also have a visible light path which is parfocal and collinear with the IR light path so that the sample can be easily viewed and positioned. The accessory can be coupled to an FTIR spectrometer by sending an external IR beam via a set of transfer optics from the interferometer into the microscope which is located to one side of a standard IR bench. Another type of instrumentation houses the interferometer, optics, and microscope all in one enclosure.

3.1 Objectives and Condensers

The objective and the condenser are the main lenses in the IR microscope accessory. Reflecting optics are typically used for these lenses in the mid-IR since they do not absorb IR light, possess chromatic aberrations, or introduce strain birefringents. Although two types can be found in IR microscopes, the on-axis Schwarzschild-type (commonly referred to as the Cassegrain) and the off-axis parabolic lens, all current models use only the Schwarzschild-type reflecting objectives. Figure 6 shows a cross-section of a typical Schwarzschild lens.

The Schwarzschild lens is used as a focusing lens, or objective, because of its high image quality and efficiency. These objectives have NAs which range from 0.28 to 0.60 and magnifications up to 36x. Although there is no dependence of magnification on signal, higher

**Figure 6** The cross-section of a Cassegrainian lens. (Reproduced by permission of Marcel Dekker, Inc. from J.E. Katon, A.J. Sommer, P.L. Lang, *Appl. Spectrosc. Rev.*, **25**, 173–211 (1989–1990).)
magnification objectives can allow the use of wider apertures to define the sample and therefore reduce diffraction effects at the aperture. However, as noted above, there is also a decrease in working distance. A standard Schwarzschild lens focuses IR radiation onto the sample with light rays ranging from $12^\circ$ to $35^\circ$.

Unique to the reflecting objective is the characteristic known as central obscuration which is defined as the light intensity obstructed by the secondary mirror to that which would have been received by the primary mirror in its absence. Central obscuration is typically minimized to values below 25%\(^2\). The obscuration has the unwanted effect of reducing image brightness by spreading the diffraction pattern. In comparison with refracting objectives, centrally obscured objectives are limited to lower magnifications and NAs.

In older microscope accessories, one might find an off-axis paraboloid serving as a condenser. But the parabolic lenses, in general, provide a poorer definition of sampling area, produce more glare, and provide a wider focal beam at the sample than the Schwarzschild condensers.\(^1\) The consequence of a larger focal diameter is that for samples smaller than the beam, more spurious energy may be introduced.

Refraction by the sample support is an important consideration in the design of the objectives and condensers. For example, when light passes from a lower refractive index medium to a higher one, the rays are bent toward the normal. The shift, which is also dependent on thickness, \(t\), is described by Equation (4):

\[
\frac{(n - 1.0) t}{n} \quad (4)
\]

where \(n\) is the refractive index of the specimen, and the refractive index of air is assumed to be 1.0.\(^3\) In a visible light microscope the objective is designed with a correction for a standard cover glass, and the condenser, for a standard glass slide. In IR microspectroscopy, the sample might lie on a variety of supports ranging from potassium chloride or zinc sulfide, to diamond or silicon. Therefore supports which have a high refractive index or which are very thick can give rise to large focal shifts. Figure 7 demonstrates that a focal shift of about 400 \(\mu\)m is observed when the support is changed from potassium chloride to zinc sulfide.\(^7\) This shift is significant considering that the typical sample thickness is usually less than 10 \(\mu\)m. Since the beam is not in focus at the sample, it cannot be focused adequately onto the detector, and the result is a decrease in the S/N and photometric inaccuracy. This focal shift can be compensated for by refocusing the condenser. The fixed off-axis system cannot be easily refocused and, thus, puts limitations on the type of sample supports and/or sampling cells one can use.

A related phenomenon is spherical aberration, due to focal shifts which arise when an IR window is placed over the sample. Some Schwarzschild objectives contain a spherical aberration correction so that the analyst may compensate for these focal shifts.\(^16\) These objectives can compensate for windows ranging from 1 mm to 3 mm in thickness.

### 3.2 Apertures

Sample definition can be obtained in two ways. One alternative is to place the sample in a pinhole.\(^17\) However, this process is a tedious and time-consuming task. The other alternative is to place and adjust remote apertures in the sample's image planes to define the sample area as previously described and illustrated. Although the placement of an aperture at the image plane is traditionally called a field stop by microscopists, the term aperture has been employed by manufacturers of IR microscopes and will be used here. In all IR microscopes an aperture is found between the sample and the detector. Yet as stated in section 2.1, spurious energy can reach the detector owing to IR light bending around the aperture's edge. To minimize the effects from diffraction, some microscopes have an additional aperture which is positioned in an image plane located between the source and the sample. It has been found
that the latter aperture is more important especially if the specimen plane is flooded with energy or if the specimen is highly scattering. The latest Spectra-Tech, Inc. design uses an optical path which results in a single aperture to effectively achieve confocal aperturing as Figure 8 illustrates.

Other microscopes have apertures made of low-E glass which are transparent to visible light, but not IR radiation. Additionally, the Perkin-Elmer AutoIMAGE microscope uses “whole field of view” apertures which keep the sample in view when masking an area of interest. The sample area is defined on its visual image using a computer “growbox”. But during spectral acquisition, motor-driven aperture blades automatically adjust to the dimensions defined by the user.

3.3 Stages

The IR microscope stage needs to accommodate samples, sample supports, and sampling cells of various sizes and shapes. Stages are available to facilitate sample positioning through different amounts of X, Y, and Z travel and can be operated manually or can be motorized for precise, accurate, and easy positioning of samples. Motorized stages, which can be interfaced with the IR spectrometer’s data acquisition software via RS-232 communications, are used routinely for mapping the sample. Samples can be stepped as small as 1 µm increments and as precisely as +/- 0.3 µm. For polarization studies a stage which can provide rotational travel or angular movement is often used. Finally, for the study of samples in controlled temperature environments as well as the study of phase transitions and liquid crystals, a heated/cooled stage is required. These stages incorporate a temperature-, moisture-, and light-resistant window, like diamond, for transmission studies and may provide a range of temperatures from 200 °C to 600 °C.

3.4 Visible Illumination and Viewing Systems

It is a requirement that the IR microscope accessory also function as a visible microscope so that the sample can be found, positioned, and focused. Since the visible microscope is especially important for examining the heterogeneity of a sample, IR microscopes need to allow for the observation of transparent or opaque samples. Consequently, the visible illumination systems must provide a light source below the sample for transmission viewing and a light source above the sample for viewing in reflection. Uniform illumination is critical for maintaining image quality and so Koehler illumination is standard on many microscope accessories. Koehler illumination results when the filament of the light source, a coiled tungsten wire, is imaged into the back focal plane of the objective. The eyepieces for viewing can range from 5 x to 20 x in magnification and often contain a reticle for the measurement of sample dimensions. Trinocular or quadnocular viewers are available which allow for simultaneous photomicrography or photomicrography and video viewing, respectively.

Figure 8 The optical diagram of the Continuum™ microscope in the transmission mode. (Reproduced by permission of Spectra-Tech, Inc.)
A wide variety of refracting, transmitting glass objectives are also used for visible viewing or photomicrography, ranging from 4× to 40× in magnification, as well as phase contrast objectives which improve the visibility of colorless samples like certain polymers or unstained biological samples. Microscopes also allow for the positioning of a visible polarizer and analyzer so that various optical properties like refractive indices, angle of extinction, birefringence, and sign of elongation can be measured. Condensers are optically matched to the visible condensers and the type can vary depending on application, such as phase contrast, polarized light, or dark-field microscopy.

3.5 Infrared Sources and Detectors
The IR source used in microspectroscopy is the same as the source on all IR spectrometers, a nichrome wire or a silicon carbide material. Both emit blackbody radiation and operate in the range from 1273 K to 1573 K. However, the standard triglycine sulfate detectors are not used because their sensitivity is too low for microscopic applications. Instead, liquid-nitrogen-cooled semi-conductor detectors are used, the most common being the MCT detector. MCT detectors have different sensitivities, and the greater the sensitivity, the narrower the detection range. For example, a wide-band MCT detector has a range down to 450 cm\(^{-1}\) while a narrow-band detector has a range up to 580 cm\(^{-1}\); however, a wide-band detector has only about 25% of the detectivity. Although MCT detectors are available with sizes ranging from 100 µm \(\times\) 100 µm up to 2 mm \(\times\) 2 mm, the 250 µm \(\times\) 250 µm is standard equipment for a microscope accessory. Most detectors are housed in the microscope assembly itself.

FPA detectors are discussed in section 6.2.

3.6 Purge
Atmospheric carbon dioxide (2350 cm\(^{-1}\) and 670 cm\(^{-1}\)) and water (3400 cm\(^{-1}\) and 1640 cm\(^{-1}\)) absorptions are often present in spectra obtained through an IR microscope. Any change in the amount of these atmospheric gases from the time the background is obtained to the time the sample scan is obtained will result in positive or negative absorptions in the spectrum. An adequate purge must be provided for the IR microscope accessory if a spectrum free from atmospheric interference is to be obtained. A purge can be provided for by enclosing the microscope in plexiglass or by a series of devices: purge enclosures for seal areas below the stage, a bellows to connect the condenser to the aperture location, purge skirt for the objective, and a flexible baffle for the top of the condenser. Short optical paths are also helpful in maintaining a good purge.

However, traditional purge problems may become negligible with the availability of software which easily and accurately compensates for various amounts of unratioed atmospheric absorptions in the spectrum. Perkin-Elmer’s Atmospheric Correction software, for example, models the absorption bands from water vapor and carbon dioxide and removes them via a mathematical treatment which not only takes into account the amount of water or carbon dioxide, but subtle band shifts which may arise.

3.7 Automation
At present, most “standard” IR microscopes are fully automated. For example, aperturing is performed interactively with motor-driven aperture blades and focusing achieved with the one touch of a computer button. There is automatic adjustment of microscope configuration between visible viewing and the IR collection mode, as well as from the IR reflection mode to the IR transmission mode. The degree of visible illumination, the position of the Cassegrainian condenser, and the visible magnification can be adjusted through computer control rather than performed manually at the microscope. Furthermore, the motorized stage has become standard equipment and is often used as a multi-sampling device in addition to mapping. Several free-standing samples are placed on the stage, their coordinates programmed into the software, and the microscope is left to find, focus, and record spectra on the individual samples.

4 BASIC TRANSMISSION TECHNIQUES AND PRINCIPLES
A common experiment performed in IR spectroscopy is the transmission experiment, the measurement of the IR radiation which has been transmitted through a sample. This experiment is performed using the IR microscope as the ray traces in Figure 1 and Figure 8 illustrate. The success of the transmission experiment, that is, the quality of the resulting spectrum, is very dependent upon sample preparation. This is because, by virtue of the microscopic sample’s size, it is essentially an optical element of the microscope.

4.1 Sampling Considerations
The ideal sample for transmission microspectroscopy is one that does little to disrupt the optical path of the IR radiation. The requirement for such a sample would be an appropriate path length so as not to produce totally absorbing bands in the spectrum, a large enough diameter so that diffraction effects are minimized, and a smooth
contour so that no scattering takes place. Consequently, any preparation of the sample serves to address one or more of this issues.\textsuperscript{19}

In macroscopic sampling, we rarely run a transmission spectrum on an undiluted sample with the exception of a thin film. The same consideration must be given to most microscopic samples; they are often too thick to obtain high-quality transmission IR spectra without reducing their path length. Using macroscopic methods, for example, any bands which possess total absorption that result from a thick sample would be readily apparent in the spectra since their transmittance is 0%. When using an IR microscope, however, total absorption may be offset by stray light effects as the spectrum of the hair fiber in Figure 3 shows. On other samples, the effects may be more subtle, and the broad, undefined bands which result may interfere with sample characterization. If one considers that, typically, a transmittance spectrum obtained on a 10-\(\mu\)m thick organic sample needs little or no ordinate expansion, then samples thicker than this will require dilution or path length reduction.\textsuperscript{5}

Reducing the path length of a microscopic solid sample can be performed by flattening the sample with a probe tip or stainless steel bearing mounted on an axle handle (called a roller) or by placing the sample in a specially designed pressure cell with IR transparent windows. A common cell used for this is the low-pressure diamond anvil cell whose diamond absorptions occur at 1900–2100 cm\(^{-1}\), a region where few other materials absorb.\textsuperscript{18} In fact, IR microscopists have found it convenient to use for flattening most samples because the cell contains the sample while flattening. Often several samples are placed on the diamond cell, flattened, and then the top diamond is removed after which the spectrum is recorded on each subsequent sample. If used in this fashion, the condenser of the microscope must be adjusted to compensate for the high refractive index of the diamond as discussed in section 3.1. If the sample is fairly elastic, pressure must be maintained to keep an adequate path length, so the spectrum must be recorded while the sample is held in place in the pressure cell. In this case, both the condenser and the objective must be adjusted so that signal is not lost owing to refraction effects. When crystalline orientation or morphology need to remain unaltered, slicing the sample to achieve path length reduction may be a better alternative. Although this can be performed by hand using a razor blade, diamond knife, or other sharp device, a microtome can be used to obtain sections of reproducible thickness.\textsuperscript{16}

Path-length concerns in the NIR region, however, are less of a problem. Since most NIR bands are a result of overtones or combinations, they are typically much weaker than their corresponding fundamental transitions, and NIR spectra can be recorded on undiluted or unaltered samples as thick as about 0.5 mm.\textsuperscript{19,20}

Fortunately, the sampling technique of flattening to reduce path length will also help to minimize diffraction occurring at the sample’s edge as well as at the apertures which are used to define the sample. Figure 9 which compares the spectrum of the cellulose acetate film (Figure 9b) with the spectrum of a 15\(\mu\)m \(\times\) 15\(\mu\)m slice of cellulose acetate (Figure 9a) illustrates the effect of sample diffraction.\textsuperscript{21} Both samples are the same thickness, and their spectra were obtained with an identical single remote aperture as previously discussed in section 2.1. Since the film is much larger in area than the area defined by the aperture, the effects from diffraction around the film’s edges are not observed. When the spectrum of the film is compared to the spectrum of the slice, one observes that the carbonyl stretch at about 1750 cm\(^{-1}\) has a peak intensity of 28\%\(T\) versus 36\%\(T\), and the C–O stretch at about 1225 cm\(^{-1}\) has an intensity of 18\%\(T\) versus 38\%\(T\), respectively. IR radiation which has bent around the slice of cellulose acetate has reached the detector, and this spurious radiation is worse at longer wavelengths in accordance with the diffraction theory described in Equation (1). Varying changes in the relative intensities are also a result of diffraction. Compare the relative intensity of the methyl bend at 1375 cm\(^{-1}\) with the C–O stretch at 1225 cm\(^{-1}\). The relative intensity is about the same in the spectrum of the cellulose acetate slice, while the 1225 cm\(^{-1}\) band is much more intense in the spectrum of the film. The longer wavelength band (1225 cm\(^{-1}\)) is bent around the sample more in the spectrum of the slice owing to diffraction, and the result is an increase in \%\(T\). Other studies clearly show that band intensity ratios change significantly as sample size gets smaller. However, distortions in band \textit{shapes} can result from effects other than diffraction. The asymmetric bands observed in the middle and bottom spectra of Figure 2, for instance, appear to be the result of specular reflections off the side of the microscopic sample.\textsuperscript{14}

As discussed in section 2.1, diffraction can occur at the aperture edges or the sample edges. One effect of diffraction around the aperture is a baseline distortion with a loss of transmission at the longer wavelengths.\textsuperscript{22} Figure 10 shows that as the aperture becomes smaller, more energy is lost.\textsuperscript{23} However, this baseline slope can be ratioed out of the spectrum by using the same aperture settings in the acquisition of the background spectrum as used in the sample spectrum. This is achieved by closing the aperture(s) down around the image of the sample particulate or area of interest, acquiring a single-beam spectrum of the sample, \(I\), then moving the stage to a vacant area of the IR window without resetting the apertures. The single-beam spectrum of the window is acquired, \(I_0\), and the two spectra are ratioed, \(I/I_0\).
Another sampling consideration familiar to IR spectroscopists is that caused by the scattering of IR radiation. An opaque, finely powdered sample or one which is rough on a microscopic scale will scatter the light, and the scattering is proportional to the square of the difference in the refractive index of the sample and the surrounding medium.\(^{24}\) Since the scattering is more marked at shorter wavelengths, the result is that the spectrum of the sample exhibits a sloping baseline. The common correction for macro samples is to suspend them in a medium which has a similar refractive index and coalescing the two into a pellet. KBr, KI, CsBr, CsI, for example, are commonly used media. In microspectroscopy such a “pellet” may be formed by placing one or two salt crystals in the sample and pressing down with a pointed probe while rolling it and applying pressure. If the probe has an area of 25 µm × 25 µm, 0.1 pounds of force on the handle becomes translated into about 100 000 lbs in\(^{-2}\) at the probe tip, well enough for an adequate pellet.\(^{25}\) In addition, the sample area is increased along with the concomitant increase in aperture size, thereby minimizing diffraction effects; the signal is increased with a resulting increase in S/N; and the sample is diluted, and thus total absorptions are less likely. Other investigators have found that scattering by opaque particles can be reduced by pressing them directly into KBr windows or suspending them in Nujol.\(^{26,16}\)

However, some workers still think the use of the diamond anvil superior. The sample preparation is simpler, and problems related to baseline slope from inadequately ground KBr are omitted, in addition to water adsorption on KBr which might prevent accurate hydroxyl group assignments.\(^{27}\)

### 4.2 Detection Limit

The eye can detect objects which are below the diffraction limit of visible light, although it may not resolve two objects which are close together.\(^7\) Therefore, diffraction does not necessarily limit the detection of a compound in IR microspectroscopy. However, as sample size
approaches the diffraction limit, the quality of the spectrum decreases owing to the loss of energy, and it may be so severe that the absorptions cannot be distinguished from the baseline.

In terms of the detection of small amounts, it depends on the sample’s shape, diameter, thickness, and absorption coefficient. Katon has obtained a high-quality transmittance spectrum on an approximate 6-ng particle of isotactic polypropylene, yet the sample was relatively smooth, approximately 10 µm thick and 25 µm wide. The thickness was optimum for a transmission experiment without any ordinate expansion, and the sample was large enough (and consequently the apertures) to not cause any significant diffraction effects.\(^{25}\)

More impressive is the report of the absorbance IR spectrum of a single, 7-µm diameter red blood cell by Dong and co-workers.\(^{28}\) Assuming the red cell has a cylindrical shape with a height of 5 µm (probably an overestimation, since red cells are characteristically concave) and an average density of 1.054 g mL\(^{-1}\),\(^{29}\) the experiment indicates a detection limit (DL) of 0.20 ng of material.

Other work has shown that transmission IR microspectroscopy is suitable for the detection of 3.6-nm to 36-nm thin organic layers on chalcogenide fibers.\(^{30,31}\) However, the authors have taken advantage of a sensitivity enhancement which results from the geometrical effects of the cylindrical fiber which serve to concentrate the transmitted radiation from the organic layer and thereby improve the S/N.

5 BASIC REFLECTION TECHNIQUES AND PRINCIPLES

In an IR microscope’s reflection collection mode, a split mirror (beamsplitter) is placed in the IR beam to allow 50% of the incident light to be delivered to the objective and focused onto the sample. The light reflected from the sample is collected by the same objective and reflected by the split mirror onto the detector. This is illustrated in Figure 5 and more explicitly illustrated in Figure 11. Depending on the nature of the sample, the analyst can perform three basic experiments when the microscope is in the reflection collection mode: specular reflection, diffuse reflection, and absorption-reflection. Specialized objectives can be installed to perform other reflection experiments, such as, ATR and grazing angle reflection.

5.1 Specular Reflection

Specular reflection occurs when the IR radiation is reflected from the front surface of an optically thick dielectric sample, and the angle of the reflected light is equivalent to the angle of incident light as Figure 12 shows. Although radiation could also be refracted and transmitted, this component is not collected. Back surface reflection could also take place, but if the sample is of the proper thickness, this component will not contribute significantly. In specular reflectance Fresnel’s relations apply to the process as Equations (5) and (6) describe:

\[
\begin{align*}
\hat{r} & = \frac{\hat{n} - 1}{\hat{n} + 1}^2 \\
\hat{n} & = n + i k
\end{align*}
\]

where \(r\) is the reflection coefficient, \(n\) is the refractive index, \(\hat{n}\) is the complex refractive index and \(k\) is the extinction coefficient.\(^{32}\) Since the specular reflectance spectrum is the plot of \(r\) versus frequency, and since the reflection coefficient follows the complex refractive index, the specular reflectance spectrum will feature discontinuity in the region of the absorption bands. These first-derivative-like spectral features, or restrahlen bands, can be observed in the top spectrum in Figure 13, a spectrum of a Nylon tie (used to fasten tubing to laboratory glassware).

A mathematical relationship known as the Kramers–Kronig integration can transform specular reflectance spectra into absorbance spectra by calculating \(k\), \(n\), and the phase angle shift, \(\theta\).\(^{33,34}\) The conventional IR absorption spectrum is then the dispersion of \(k\), a plot

---

*Figure 10* The effect of diffraction caused by small apertures. Spectra A to F correspond to spectra obtained using 29, 25, 21, 17, 12.5, and 8.3 mm (actual) diameter apertures, respectively. (Reproduced by permission of Royal Society of Chemistry from P.H. Turner, Anal. Proc., 23, 268, 1986.)
of $k$ versus frequency. The bottom spectrum in Figure 13 shows the transformed spectrum of the Nylon tie. The large negative feature at about $3600$ cm$^{-1}$ is an anomaly and indicates that the sample was not a perfect specular reflector. In fact, although the sample was optically thick, it was not completely smooth, and one could observe a visible grain in the sample which effected diffuse, random reflections. Although not in this spectrum, another common anomaly that might occur is when unrationed carbon dioxide or water vapor absorptions remain in the specular reflectance spectrum. Those absorption bands will be distorted after the KK transformation since the mathematical treatment presumes all bands result from specular reflection.

Sample preparation for this type of experiment is minimal. A sample is usually placed on top of a microscope slide and placed on the stage of the microscope accessory. The sample area is then defined by the use of one or more remote apertures, and the spectrum acquired. The background spectrum is obtained on a smooth, highly reflective, nonabsorbing surface such as a front-coated gold mirror using the same aperture setting. (This was how the spectra shown in Figure 13 were acquired.) Another sampling method suitable for the study of minerals is to embed the sample in an epoxy resin and polish the surface. Regardless, specular reflection is a low-efficiency process, and therefore the largest sample area possible should be used so that an adequate S/N is obtained.

5.2 Diffuse Reflection

When an absorbing sample is dispersed in a nonabsorbing media, the incident radiation is transmitted through sample particulates and is diffusely reflected off the nonabsorbing particulates, such as ground KBr, as illustrated in Figure 12. This is the diffuse reflection experiment, and it can also be performed with a standard Schartzschild lens in the reflection collection mode. The diffuse reflectance spectrum, $R'_\infty$, is defined as the ratio of the single-beam diffuse reflectance spectrum of the sample to that of a nonabsorbing standard. The Kubelka–Munk theory indicates a linear relationship between the diffuse reflection function, $f(R'_\infty)$ and the sample concentration, $c$, according to Equations (7) and (8):

$$R'_\infty = \frac{R'_\infty \text{(sample)}}{R'_\infty \text{(std)}}$$

$$f(R'_\infty) = \frac{(1 - R'_\infty)^2}{2R'_\infty} = \frac{c}{k}$$
where \( k = s/(2.30e) \), \( s \) is the scattering coefficient, and \( e \) is the molar absorptivity. Therefore, one would expect the spectrum, \( f(R^{\infty}) \) to be similar to an absorbance spectrum as Figure 14(a) shows. After the calculation of the Kubelka–Munk spectrum shown in Figure 14(b), however, the corrected relative intensities are more similar to that of an absorbance spectrum.

Diffuse reflection can vary a great deal with particle size. To minimize this effect, uniform KCl particles which range between 75 µm and 90 µm are recommended because they show little variation in reflectance over the mid-IR region from 2 µm to 20 µm. Another caveat is that if the sample is too concentrated or undiluted, specular reflections may greatly contribute to the spectrum, resulting in the restrahlen features discussed in the previous section. Finally, since microscope optics are not maximized for diffuse reflectance experiments, one needs to obtain the spectrum using the widest apertures possible, in order to maximize energy and consequently S/N.

A typical sample preparation for the microscope accessory is to roughen the surface of the sample with a fine grit emery paper or diamond abrasive paper with the appropriate particle size. The spectrum of the ground sample left on the paper is obtained and ratioed against a spectrum of unused emery paper at the same aperture settings. (This was how the spectra shown in Figure 14 were obtained.) Alternatively, the roughened surface of the actual sample could be analyzed. Diffuse reflectance spectra of dyes separated by thin-layer chromatography have been obtained using the IR microscope.\(^{36}\)

### 5.3 Absorption/Reflection

If a sample of the proper thickness is in intimate contact with a reflective surface, a absorption-reflection experiment can be performed when the microscope is in
the reflection collection mode. As illustrated in Figure 12, the incident light passes through the sample, is reflected off the surface, and passes back through the sample again before collection. Since absorption-reflection is approximately a double-pass transmission experiment, the maximum sample thickness is estimated at about half that for the sample measured in transmission. Given that the Schwarzschild objective delivers light at an average incident angle of 25° from the normal, the sample thickness which yields a spectrum with little or no ordinate expansion is estimated at 4.5 µm according to Equation (9):

\[ 2d = 10 \cos \alpha \]  

where \( \alpha \) is the angle of incidence and \( d \) is the thickness of the film. Although light also reflects at the front surface of the sample, this contribution to the overall reflection will vary depending upon the sample’s properties. If the contribution is large, restrahlen bands will be observed. Ideal samples for absorption-reflection experiments are also relatively smooth and flat, and typically tend to be coatings, films, or film-like deposits on metal.

Special objectives can be added to the IR microscope which will deliver the incident light at grazing angles, typically at a range from 65° to 85° as Figure 15 shows. According to Equation (9), measurement at a grazing angle can allow for the analysis of extremely thin films on reflective surfaces of 1 µm or less. The microscope objective offers the capability to obtain spectra on samples microscopic in dimensions in which the nominal area is approximately 50 µm \( \times \) 50 µm. The Spectra-Tech grazing angle objective, for example, has 30 \( \times \) magnification, a NA which ranges from 0.996 at 85° to 0.51 at 33°, a working distance of 1 mm, a viewing mode, and an option for an IR polarizer. It is important to note that Pepper has found that the grazing angle objective is suitable for quantitative measurements; that is, there is effectively no angular dependence on the incident light intensity.

5.4 Attenuated Total Reflection

A more widely applicable technique for IR microspectroscopy is ATR. To perform this experiment, a special objective can be added to the IR microscope which contains an internal reflection element of relatively high refractive index as Figure 16 shows.

When the IR radiation is introduced into the element, it can be total internally reflected if the incident angle is greater than the critical angle \( \theta_c \) according to Snell’s law described in Equation (10):

\[ \theta_c = \sin^{-1} \left( \frac{n_1}{n_2} \right) \]  

where \( n_2 \) is the refractive index of the element, and \( n_1 \) is that of medium with which it is in contact. Although complete internal reflection occurs at the interface between the two media, radiation does in fact penetrate into the rarer medium, and a sample placed in contact with the element may absorb this radiation at the point(s)
of reflection. In contrast to specular reflection, ATR is a very efficient technique with virtually no loss of energy except from absorption by the medium. The standing wave established at the point of reflection is called the evanescent wave and is described by Equation (11):

\[ d_p = \frac{\lambda}{2n_e \sin^2 \theta - n_{\text{rec}}^2}^{1/2} \]  

\( d_p \) is the depth of penetration, \( \lambda \) is the wavelength, \( \theta \) is the angle of incidence, \( n_e \) is the refractive index of the element, and \( n_{\text{rec}} \) is the ratio of the refractive index of the sample to that of the element. Thus greater penetration depths are achieved for a particular angle of incidence by altering the internal reflection element. Internal reflection elements such as zinc selenide (\( n_e = 2.4 \)), offer a greater penetration depth than germanium (\( n_e = 4.0 \)), for example. At incident angles of approximately 45° and assuming 1.5 for the sample’s refractive index, this corresponds to a depth of 0.2 \( \lambda \) and 0.066 \( \lambda \), respectively, and offers the possibility to obtain spectra at the surface of a sample. However, if the sample is multilayered or lies on an absorbing substrate, the sample needs to be at least as thick as the depth of penetration, otherwise the medium under the sample will be detected. If a sample is completely transferred to the element and is thinner than the penetration depth, the spectrum of the entire sample will be obtained, not just the surface.

The ATR objective with magnification of 25× allows for sampling the surface of a microscopic sample with a nominal area of 50 \( \mu \)m by 50 \( \mu \)m. The small area of the microscope ATR element in combination with the single bounce reflection has the advantage that complete contact of the sample with the element is more easily achieved. Consequently, baseline distortions associated with the uneven, lower pressures which result from using macroscopic ATR elements are eliminated.(38) In addition, Reffner and Martoglio report another advantage.(16)

In the Spectra-Tech ATR objective, which has a hemispherical shaped element, the cross-sectional area of the radiation passing through it is magnified by the refractive index of the element. Using a germanium element, for instance, a 2.50 mm diameter circular aperture in the image plane corresponds to an apparent sample diameter of 100 \( \mu \)m but is an actual sample diameter of 25 \( \mu \)m. Thus, for a germanium ATR microelement, an aperture four times larger than what is usually required for a sample can be used, reducing the diffraction problem at the aperture considerably. This magnification factor associated with micro ATR elements has been verified for samples 60 \( \mu \)m in diameter and larger.(38)

Another theoretical consideration is that since the sample is immersed in the internal reflection element, the spatial resolution should be increased according to Rayleigh’s criterion given in Equation (1). This is because the refractive index, \( n_1 \), of the medium is increased, and therefore NA is increased according to Equation (2). However, since only half of the beam is introduced into the objective and collected by the objective when the microscope is in the reflection collection mode, the spatial resolution using an ATR element will theoretically only increase by \( n_1/2 \). (38)

Sample preparation is typically nonexistent using the ATR objective. The sample is brought into view and positioned using a refracting lens which is built into the middle of the ATR objective as Figure 16(a) shows. Then with the slide selector in the intermediate position, Figure 16(b), the stage is adjusted to bring the sample in contact with the internal reflection element by either visual observation or by using an automated pressure sensor. After defining the sample area to be analyzed using a remote aperture, IR radiation is then directed into the internal reflection element as Figure 16(c) illustrates, and a sample spectrum is obtained. The sample spectrum is ratioed to a background spectrum obtained while the objective is not in contact with the sample. Since spectra can be obtained so easily using a micro ATR objective, and because the ATR spectra have equivalent S/Ns as those obtained in transmission on samples of the same size, the use of ATR microspectroscopy has become more widespread.(38)

6 INFRARED IMAGING SYSTEMS

6.1 Traditional Mapping

Using a motorized stage, IR imaging can be performed with a standard MCT detector and microscope accessory in either the reflection or transmission collection mode. IR spectra can be obtained for a contiguous sample area by stepping the stage (a computer-controlled operation) in small increments which are the same as or less than the effective aperture size and recording the spectrum at each step. The corresponding mapping software then plots the intensity of an IR absorption band or absorption band ratio as a function of x-y coordinates, displaying the images as wire frame or contour plots as Figure 17 illustrates.(31) In this fashion, a particular functional group’s concentration is mapped across a heterogeneous sample. One can also opt to collect spectra in a straight line across a sample as Figure 18 illustrates.(39)

The main problem associated with mapping is the long collection time. If a high-quality spectrum takes 10 s to obtain at each stage increment, then a map formed from a 64 \( \mu \)m × 64 \( \mu \)m spectral grid (4096 spectra) will take approximately 11 h to obtain. This could correspond to a 225 \( \mu \)m × 225 \( \mu \)m sample stepped across in increments of 15 \( \mu \)m, for example. Another problem, mentioned in section 2.1, is that owing to diffraction at the aperture(s)
edge, there will be spectral contamination from surrounding areas in each spectrum. However, it has been suggested that if the step size is significantly smaller than the effective aperture size (for example, 3 µm versus 15 µm, respectively) that the effective spatial resolution can be increased if chemometric methods are employed in conjunction with mapping. Harthcock has shown that factor analysis of the data can reveal the number of spectrally different layers of a polymer laminate, even when the width of one or more polymer layers is below the diffraction limit, providing that linear additivity holds and experimental noise is within reasonable limits. However, sampling will take considerably longer under these conditions.

6.2 Focal Plane Array Detectors

Spatial and spectral information can now be collected simultaneously using a step-scan interferometer coupled with an IR microscope and a FPA detector. The FPA detectors consist of a grid of very small IR detectors each of which can detect radiation from different locations of the sample. Thus, at each detector element a NIR or mid-IR spectrum is obtained for each region of the sample. One can either observe the spectrum at a particular pixel which corresponds to a particular sampling region or observe the intensity of a particular absorption band for each pixel as Figure 19 shows.

FPA detectors can be fabricated from a small selection of materials including platinum silicide (1.0–5.7 µm), palladium silicide (1.0–3.2 µm), iridium silicide (1.0–8.2 µm), indium antimonide (1.0–5.5 µm), indium gallium arsenide/indium phosphorus (1.0–1.7 µm), germanium (1.0–1.6 µm) and MCT (2.5–12 µm). Digilab’s Stingray FPA detectors, for example, are constructed of either
Plot absorbances for each pixel at a given frequency

Plot absorbances for each frequency at a given pixel location

**Figure 19** Illustration of a “stack” of FPA data. (Reproduced by permission of Spectroscopy from J.L. Koenig, C.M. Snively, ‘Fast FTIR Imaging: Theory and Applications’, *Spectrosc.*, 13(11), 22–28 (1998).)

a 128 × 128 InSb element grid or a 64 × 64 MCT element grid for work in the NIR region or mid-IR region, respectively. Past instrumentation has been designed using an FPA detector configured with an acousto-optical tunable filter (AOTF)\(^{43}\) or a tunable bandpass dielectric filter\(^{44}\) which allows for selection of a wavelength which corresponds to a specific absorption band by changing the spectral bandpass. The imaging process occurs by selecting a wavelength, collecting a spectrum, and then repeating the process. The AOTF and dielectric filters are limited to the very near IR region (10,000–5000 cm\(^{-1}\)) and the NIR region (4000–2300 cm\(^{-1}\)) respectively.

More recently, FPA detectors have been used with a step-scan interferometer since as many as 16,000 outputs must be read simultaneously at each retardation interval of the interferometer.\(^{45,46,47}\) Standard rapid-scanning interferometers which measure the output from a single detector, scan at speeds ranging from millimeters per second to centimeters per second. Since this is too fast to obtain acceptable S/N from the less-sensitive FPA detectors, radiation must be collected over a longer time period. Consequently, at each step of the interferometer, several image frames are obtained and co-added as needed to obtain adequate S/N. Although the time required to Fourier transform and ratio to background is several minutes of processor time, the time required for the collection of 4096 spectra (16 cm\(^{-1}\) resolution, 150 co-added image frames during each 1 second interferometer step, 255 steps, 1 scan) is less than five minutes.\(^{46}\)

Other than a marked decrease in the collection time of the image, the use of FPA detectors can, in theory, increase the spatial-resolution capabilities of the IR microscope. Since IR spectra are collected across an unapertured sample, there is no diffraction by the aperture. The size and number of individual detector elements in conjunction with the optical configuration define the spatial resolution.\(^{42}\) For example, if a sample of 500 µm × 500 µm dimensions is focused onto a 64 × 64 detector, each pixel collects information from a 7.8 µm square region of the sample.

Although the image quality and speed are superior using FPA detection, the lower sensitivity of the FPA detectors, often results in individual spectra with lower S/N ratios than spectra obtained mapping with a single-point MCT detector. Furthermore, although it is possible to obtain spectra at spectral resolutions of 4 cm\(^{-1}\) or higher using FPA detection, it is currently not practical owing to the difficulty of handling large data sets generated at higher spectral resolutions.\(^{41}\)
7 PERSPECTIVE AND FUTURE DEVELOPMENTS

7.1 Spatial Resolution Below the Diffraction Limit

The relatively recent coupling of an IR microspectrometer with the IR radiation emission from the National Synchrotron Light Source has shown a significant increase in spatial resolution and S/N performance.\(^{(48,49)}\) This result is due to the source being highly collimated and small, 200 µm by 400 µm, it is 100 to 1000 times brighter than from a 1500 K thermal emission source. Experiments have shown that using 6 µm × 6 µm dual remote apertures, the synchrotron system clearly resolved 4 µm layers in a cross-section of a multilayered laminate and provided a S/N greater than 200 : 1.\(^{(50)}\)

Spatial resolution can also be improved through the use of pseudo near-field techniques where a small aperture is placed in contact, or nearly in contact, with the sample.\(^{(51,52)}\) IR mapping can be performed if an aperture turret is constructed to allow for x-y motorized stage movement.\(^{(52)}\) In both cases, the aperture effectively prevents the light from spreading into a diffraction pattern. Although the technique substantially enhances the spatial resolution, it generally requires more alignment and increased data-collection times. A related, more elaborate technique is near-field optical microscopy (NFOM) where the evanescent field created by total internal reflection, the near-field, is modulated by the sub-wavelength details of a sample’s surface. The modulated field is then detected by the tip of a tapered glass fiber, and an image is constructed when the tip scans the surface by a stepping device. The image is dependent upon both the topography and the sample’s absorption properties. The NFOM is an important spectroscopic technique, since theoretically the size of the fiber’s tip can control the lateral spatial resolution. Piednoir and Creuzet describe a photon scanning tunneling microscope adapted to perform NFOM in the IR range.\(^{(53)}\) Their experiments suggest that with improvements in the fabrication of the probe, an increase in sensitivity can be achieved along with the concomitant improvement in spatial resolution.

7.2 The Eighth Age of Infrared Spectroscopy

In the 1973 editorial, ‘The Seven Ages of an Analytical Method,’ Herbert Laitinen, Editor of Analytical Chemistry, wrote that IR spectroscopy had reached its seventh age.\(^{(54)}\) At this stage of analytical development, according to Laitinen, a technique was at the end of its useful life and was gradually being replaced by better analytical methods. But much to the delight of IR spectroscopists, nothing could have been further from the truth. In fact, shortly after the publication of the editorial, IR spectroscopy began to experience an age of explosive growth as a result of the development of the FTIR spectrometer. Noted vibrational spectroscopist, Dr. Bruce Chase, has introduced the idea that vibrational spectroscopy, in general, has undergone an “Eighth Age” of analytical development.\(^{(55)}\) In regard to IR spectroscopy, the Eighth Age manifested itself in the development of many sophisticated sampling methods including, but not limited to, reflectance spectroscopy(s), photoacoustic spectroscopy, IR emission spectroscopy, gas chromatography linked to FTIR spectrometry, and IR microspectroscopy. Each IR sampling method has its own development that can be described by Laitinen’s Ages: experimental measurements in the research lab establish validity of the method, the instrument is introduced into the general laboratory where nonspecialists perform the measurements, the method is accepted and in competition with existing methods, applications appear in a wide variety of scientific areas, and applications become standard methods. Furthermore, because IR microspectroscopy is IR spectroscopy on the microscopic level, we are not surprised that it can be further broken down into its many sampling methods (sections 4, 5, and 6) each of which has gone through a “mini-life” of ages. These factors, among others, account for the explosion which Chase refers to as the Eighth Age.

Real-time IR imaging is the newest IR microspectroscopic sampling technique. The validity of the method is being established, it is beginning to be introduced into the general lab, and is offering some competition to traditional mapping techniques. Future developments in uncooled FPA detectors for both the near- and mid-IR regions will allow for higher pixel densities, ease of accessibility, and reduced cost.\(^{(56)}\) Thus real-time imaging using the IR microspectrometer may well become routine for many applications, including medical diagnoses and NIR quality control.

In this article, after reviewing the different mathematical methods used in quantification we will describe and discuss their respective advantages and inconveniences. First of all, different examples of applications of infrared (IR) spectroscopy, used with or without other analytical chemistry methods, will be presented. Some examples of direct quantitative analysis in food analysis will be reviewed: lipids (measurement of unsaturation degrees, lipids determination), carbohydrates, proteins (secondary structures, quantitative analysis). We will also focus on original examples of the use of IR spectroscopy combined with enzymes.

Secondly, some examples of Fourier transform infrared (FTIR) analysis coupled with other analytical methods are reviewed in the following fields: FTIR quantification in pharmaceuticals, petroleum, paints and other industrial products and in the fields of health, environment, and trace compounds analysis.

Finally, we will discuss the limitations and perspectives of IR spectroscopy for quantitative analysis. It appears that the most significant developments in the field of quantitative analysis will most probably come through progress in chemometrics and flow analysis (FA) (automation).

1 INTRODUCTION

Absorption spectrometry investigates the interactions between radiation energy and samples. The frequencies, or wavelengths, at which samples absorb radiation and the corresponding absorption intensities, are hereby recorded into a spectrum. These intensities are measured in terms of absorbance, whose values reflect the amount of radiation absorbed by the sample while the amount of radiation which travels through a sample is termed transmittance.

Since functional groups are known to absorb light at specific wavelengths, investigating absorption frequencies provides a means for elucidating chemical compositions. The constitution of an unknown sample can be investigated through the study of its wavelength/absorption spectrum. Investigating the chemical composition of unknown samples in spectrometry is commonly termed qualitative analysis.

It is sometimes useful to go beyond qualitative analysis when one is concerned with the amount of a constituent in a sample. This is commonly known as quantitative analysis.
The intensity of an absorption band is linked to the concentration of its associated constituents in a sample. A calibration model links changes in the concentration of the constituent to variations in absorbance. As a matter of fact, calibration models can be successfully used for the quantitative analysis of constituents in samples.

Near infrared (NIR) extends immediately after visible red light, from 700 nanometers (nm) to 2500 nm or, when expressed in cm\(^{-1}\), from 14,285 to 4000 cm\(^{-1}\). NIR spectroscopy is the most commonly used method for quantitative analysis of major biochemical constituents in food industry. The diversity of products that are analyzed with classical systems such as pellets or liquid cells weakly penetrates solid samples. As a matter of fact, calibration models can be successfully used for the quantitative analysis of constituents in samples.

Water is a major constituent in biological products and strongly absorbs MIR radiation. MIR spectra are complex and each functional group contributes to the spectra, which results in numerous bands overlapping. However, the advent of FTIR spectroscopy, coupled with the use of powerful computers and the advent of new techniques such as FA and attenuated total reflectance (ATR), have considerably promoted the use of MIR spectroscopy.

Figure 1 shows the evolution of the scientific literature on quantitative analysis by IR spectrometry and, as can be seen, we are nowadays at the beginning of a new era of quantitative IR. The use of computers has revolutionized studies in many aspects of biological sciences. Data analysis is a relatively new technique which only became popular from the 1960s onwards. The need for data analysis emerged from scientific disciplines, like physics or analytical physical chemistry, where workers had to manipulate considerable amounts of data. At the same time the computer appeared. It was thereby possible to process a considerable amount of data with great speed.

Data analysis is useful for investigations in which numerous variables occur; the terms multivariate analysis or multi-criterion analysis are used. These call upon mathematical spaces containing \(n\) dimensions. However, for a long time computers have remained for a long time the privilege of specialists. The advent of more and more powerful microcomputers has allowed the introduction of these multidimensional analyses into research laboratories.

Statistical data analysis has been applied to IR spectral data only recently with the advent of Fourier transformed spectrometry in the late 1970s. It follows that this IR technology particularly generated the ideal data required by these statistical methods.

Figure 1 Evolution of the scientific literature on quantitative analysis by IR spectroscopy.
Several mathematical methods can be used for processing IR spectral data in the context of qualitative or quantitative analysis.

In this article, we will first review the different mathematical methods used in quantification and discuss their advantages and inconveniences. We will then describe different example applications of IR spectroscopy used with or without other analytical chemistry methods for the analysis of foods, pharmaceuticals, petroleum products, paints, etc. Original examples of the use of IR spectroscopy combined with the use of enzymes will be also presented. The future prospects of this technique will be discussed.

2 QUANTIFICATION METHODS

In this section, we will describe the most commonly used mathematical methods in IR-based quantitative analysis. Some methods are univariate (solve only one equation based on one measured value and have one calibration value per sample), whereas others are multivariate (solve a series of equations using many measurements per sample for one calibration value). Duckworth\(^{(15)}\) has extensively reviewed these methods.

2.1 Selection of the Analysis Region

The choice of the spectral region which correlates best to the concentrations of the constituents to be predicted is one of the most delicate steps in the elaboration of the method of quantitative analysis. Generally, candidate wavelengths or spectral regions are initially chosen among those that are attributed to a constituent. This selection is usually subsequently refined through an iterative process.

The mathematical model that is then used for calculating the concentrations of constituents in unknown samples in quantitative analysis methods is the one determined by the calibration.

2.2 Classical Quantification Methods

2.2.1 Application of the Beer–Lambert Law

The principle of quantitative analysis is that intensities of absorption peaks (absorbance units) are correlated to the amount of constituents. The Beer–Lambert relationship shows that not only are the peak intensities linked to the samples concentrations but that there is also a linear relationship between them, as indicated by Equation (1):

$$A = \varepsilon cl$$  \hspace{1cm} (1)

where \(A\) is the absorbance, \(\varepsilon\) the molecular extinction coefficient (mole\(^{-1}\) L cm\(^{-1}\)), \(c\) the concentration (mole L\(^{-1}\)) and \(l\) the width of the sample (cm) or the bandpass of the cell.

The intensity of an nonoverlapped characteristic absorption band of a compound is hence a function of the concentration of this compound. A calibration model links changes in concentrations to changes in absorbance through the existence of a characteristic constant (the molecular extinction coefficient) and taking into account the bandpass (\(l\)).

In cases of substances that do not interact, only one calibration standard is necessary to calculate with precision their concentrations in an unknown sample.

For samples with broad concentration ranges, the calibration is performed on several standards with varying concentrations of the quantified constituent. Spectra of standards are measured so as to determine the absorbance values at each characteristic peak.

In the simplest case, a linear calibration model is obtained: this is the calibration curve. The concentration of an unknown sample can then be easily derived from its absorbance values.

The most commonly used method for calculating a calibration equation is multilinear regression. To calculate calibration equations, several other methods have been developed: least squares regression model, classical least squares model (CLS) and inverse least squares (ILS) model, both using simple or weighted factors.

2.2.2 Multiple Linear Regression

The use of multiple linear regression for determining calibration equations is now well established, as described by several authors. When the data to be predicted are quantitative, the prediction is performed using multilinear regression equations that link calibration data to spectral data. Honigs\(^{(16)}\) and Osborne and Fearn\(^{(17)}\) have extensively reviewed the use of this method in IR spectroscopy.

The basic principles are summarized below:

The simplest equation that can be established is of the type of Equation (2), where \(C\) is the concentration to be predicted, \(A_l\) is the absorbance at wavelength \(l\), and \(a_0\) and \(a_1\) are the regression coefficients:

$$C = a_0 + a_1A_l$$  \hspace{1cm} (2)

The wavelength \(l\) should be chosen in order to best predict the concentration \(C\).

However, equations of the type of Equation (2) are only applicable for predicting the concentration of one constituent per sample. They would not be convenient for predicting concentrations of other constituents in a mixture where interactions between constituents that absorb at similar wavelength were not taken into account.
In order to take into account these interactions, multilinear regression has been introduced, which is useful for the determination of the concentration of several compounds.

The equation to be used is then as Equation (3):

\[ C_j = a_{0j} + a_{1j}A_1 + a_{2j}A_2 + \cdots + a_{nj}A_n \]  

where \( C_j \) is the concentration of each one of the compounds to be determined, \( A_1 \) are the absorbance values measured at wavelengths from 1 to \( n \), and \( a_{ij} \) are the regression coefficients corresponding to each compound \( j \), from 0 to \( n \).

This equation is known as a calibration equation or prediction equation. The absorbances \( A_1 \) are the predictive variables and \( C_j \) is the predicted variable. The coefficients \( a_i \) can be positive or negative terms and can account for interactions between constituents.

Wavelength selection is the main problem in spectroscopic analysis, and wavelength values must be selected in order to be the ones most characteristic of the compounds to be determined and to provide noninterfered data for the compounds. Additionally, in the case of IR analysis, it is necessary to establish an appropriate baseline for the IR spectrum, which could minimize the band overlapping.

The establishment of prediction equations is generally a step-by-step process. The wavelengths are selected as a function of their predictive ability. There are large absorption bands in IR spectra and the data are strongly correlated between them. Wavelength selection is actually not an easy task: replacing a spectral data point by an adjacent one may have no effect on the prediction equation.

To reduce this inconvenience, several prediction equations are retained and tested. The most predictive equation is experimentally determined by testing validation samples.

Prediction equations can also be derived from the first-order and second-order derivative of the absorption zero-order spectra. The first derivative eliminates the general intensity effect of the spectrum and simplifies the baseline selection and the second derivative removes the slope effect.

However, the use of derivative FTIR strongly affects the sensitivity of spectrometric measurement, and thus it must be avoided when constituents are present in the sample at very low concentration values.

Derivation also improves the identification of absorption bands. The selection of the wavelength is thus simplified and the prediction equations obtained give satisfactory results.\(^{(17)}\) The quotients of first or second derivatives have also been tested in a simple regression for predicting quantitative values. The inconveniences of these derivation methods are the choice of the calculation steps and, for the quotients of the derivatives, the choice of the terms.

Multilinear regression applied to diffused reflected MIR has only been developed in a few cases. These examples show that it is possible to measure concentrations with satisfactory correlation coefficients.

The use of multilinear regression may lead to prediction equations that are unstable due to the nature of the spectral and quantitative data. The calibration of an instrument, step by step, by multilinear regression does not allow the control of the validation of the prediction equation. The interpretation of the selected wavelengths is not always easy and provides little information on the nature of the samples, owing to possible correlations between quantitative chemical data and spectral deformations.

Prediction equations that have been established from absorbance values do not completely take into account spectral deformations. This problem can be partly solved by using second derivatives.

Another inconvenience of step-by-step multilinear regression, applied to collections of continuous spectra, is that the number of data to be processed is considerable. McClure et al.\(^{(18)}\) proposed that the corresponding Fourier coefficients should be calculated. In fact, it was shown that less than 100 coefficients are necessary to describe a spectrum. The selection of the variables of the prediction equation is then performed on these Fourier coefficients. The results of McClure are of similar precision to those obtained by traditional methods. The search for the regression terms is hereby simplified due to the diminution of the number of variables analyzed.

2.2.3 Least Squares Method

The adjustment of the curve following the least squares criterion is based on a linear model. A spectrum \( S \) can be expressed as a linear combination of spectra of its constituents, Equation (4):

\[ S = S_{j=1}^n a_j c_j \]  

where \( j \) is the number of constituents, \( c_j \) the concentration of the \( j \)th constituent and \( a_j \) the coefficients obtained for each constituent.

The adjustment of the curves following the least squares criterion is performed as follows: the spectra of pure constituents are measured and the coefficients \( a_j \) of the linear combination are calculated by multiple linear regression. The constituents’ concentrations are thereby calculated using the coefficients \( a_j \) instead of the absorbances as in the stepwise multilinear regression. The advantages and inconveniences of the method are summarized in Table 1.

2.2.4 Classical Least Squares Model

This method is based on the use of Beer’s Law to extend the calculation of the absorption coefficients across a
Table 1 Advantages and disadvantages of least squares regression

<td>Calculations are very fast</td>
<td>Cannot be used for complex mixture samples in which the individual constituents have overlapping spectral bands</td>
</tr>
<tr>
<td>Used primarily for simple samples: pure compounds, binary mixtures, etc.</td>
<td>Band selection can be difficult or impossible if spectrum of property of interest is not known</td>
</tr>
<tr>
<td></td>
<td>Selecting correct polynomial can be difficult; most spectroscopic systems can be solved with a simple straight line, but this is not 100% true</td>
</tr>
<tr>
<td></td>
<td>Large prediction errors will result from constituents with bands in the same region of the spectrum as the calibration band(s)</td>
</tr>
</tbody>
</table>

Beer’s law is rewritten as Equation (5):

$$A_l = K_l C$$  \(5\)

where the absorption coefficient and path length are combined into a single constant \(K\). Measuring the absorbance of a single sample of known concentration and using these values to solve for \(K\) can easily solve this equation. Predicting the concentration of an unknown sample is as simple as measuring the absorbance at the same wavelength and rearranging Equation (5):

$$C = \frac{A_l}{K_l}$$

Typically, the CLS calibration method is most useful when applied to samples that have minimal or no inter-constituent interactions. The primary application for CLS has been in the analysis of gas-phase samples.

Table 2 below summarizes the advantages and disadvantages of this method.

</tr>
</tbody>
</table>

2.2.5 Inverse Least Squares Model

If the concentrations of all the constituents in the mixtures are not known, there may be a significant error when solving for the absorption coefficients of the known constituents by the CLS approach. One solution to this problem is by rearranging Beer’s law and expressing it as Equation (6):

$$C = \frac{A_l}{\varepsilon/\ell}$$  \(6\)

or, by combining the absorption coefficient \(\varepsilon/I\) and the path length \(\ell\) into a single constant as with CLS, express it as Equation (7):

$$C = PA_l + E$$  \(7\)

where, as before, \(C\) is the constituent concentration, \(A_l\) is the absorbance at the wavelength \(\ell\), and \(E\) is a matrix of concentration (not absorbance) errors.

Because it is not necessary to know the composition of the training mixture beyond the constituents of interest, the ILS method is better suited to more complex types of analysis not handled by the CLS approach. This method has been used for samples ranging from natural products (such as wheat, wood, cotton and gasoline) to manufactured products.

The major features of this method are summed up in Table 3 below.

---

Variables are linear combinations of all the original variables and have the advantage of having no correlation with each other. Simpler descriptions of data sets are thus obtained with minimal loss of information. These treatments were used for morphological analysis of spectra and for graphical representation of spectra similarity.

PCA is applied to the full spectra that are centered prior (to PCA) according to Equation (8):

\[ X_i = A_{ij} - A_j - A_1 + A \]

where \( X_i \) = centered data; \( A_{ij} \) = spectral data (log 1/R) of spectrum \( i \) and wavelength \( j \); \( A_j \) = mean value of spectral data at wavelength \( j \) for every spectrum; \( A_1 \) = mean value of spectral data of spectrum \( i \) for every wavelength; and \( A \) = average mean of all spectral data in the collection.

Principal component regression (PCR) was used to establish a prediction equation. PCR is basically a multilinear regression applied to scores and loadings assessed by PCA, being the coordinates of data in the new orthogonal axis and the loadings of the directional vectors of the new axis related to the preceding ones. Interest in the introduction of scores according to their predictive ability has already been shown.

Concentrations are predicted according to Equation (9):

\[ C_{nl} = X_{n,k} V_{k,p} R_{pl} \]

where \( C \) is the column vector of predicted concentrations, \( X \) is the centered matrix of spectral data, \( V \) is the matrix of latent vectors of PCA, and \( R \) is the column vector of the regression coefficients of the prediction equations.
satisfactory precision for the estimation of the chemical variable is obtained.

The new spectrum $S$ is rewritten as Equation (10):

$$ S = S + S_a c_i + r $$

where $S$ is the mean spectrum of the collection, $a_i$ the $i$th factorial coordinate, $c_i$ the $i$th factor and $r$ the residual.

The factors are estimated while calculating the chemical data coordinates and can be written as Equation (11):

$$ p = p + S_a d_i + r p $$

where $p$ is the mean value of the chemical data, $a_i$ is the $i$th factorial coordinate calculated by the equation, $d_i$ is the $i$th factor associated with the chemical data, and $r p$ is the residual.

The $d_i$ factors are estimated during the calculation of the coordinates similarly to the $c_i$ factors defined above. The chemical values for an unknown sample are estimated by calculating $a_i$, the factorial coordinates, with Equation (10) and then by applying Equation (11) so as to determine the values of $p$.

There are actually two versions of the PLS algorithm: PLS-1 and PLS-2. The differences between these two methods are subtle but have very important effects on the results. Like the PCR method, PLS-2 calibrates for all constituents simultaneously: one set of scores and one set of eigenvectors or loadings are obtained for calibration during the spectral decomposition. Therefore, the calculated vectors are not optimized for each individual constituent. In PLS-1, a separate set of scores and loading vectors is calculated for each constituent of interest. The method should give more accurate predictions than PCR or PLS-2.

Table 5 summarizes the advantages and disadvantages of the PLS methods.

2.3.3 Comparison of Partial Least Squares and Principal Component Regression Methods

It should be noticed that a spectrum obtained by least squares curve adjustments is in fact a product of spectra similar to the additive model in PCA. The resulting spectra are similar to eigenvectors and the variables with which they are associated are calculated. However the variables and the spectra are not orthogonal. The major advantages of PCA over least squares methods are the orthogonality of the factorial coordinates, but, most importantly, it calculates typical spectra and hence extracts the major characteristic wavelengths.

In the method of Hruscka and Norris,(27) the calculation basis from the typical spectra must be chosen. Even if they are carefully selected so as to be as different as possible, they are nevertheless less dissimilar than eigenvectors and thus do not detect the most characteristic frequencies of constituents. As a matter of fact, PCA is a more informative method than least squares curve adjustment methods.

The PLS method is interestingly similar to PCA, since factors and coordinates are calculated. The difference lies in the mode of calculation. Data are estimated as a function of the characteristic parameters to be measured. As a consequence, the first calculated coordinates are more predictive. With regard to this, PLS is more powerful than PCA since the information on the first axes is more predictive. However, Martens and Jensen(26) showed that the total number of axes introduced into the regression is identical and that the precision is similar. The two methods are almost identical with regard to the underlying theory is simpler than PLS. Hence modeled spectra are easier to interpret.

3 MEASURED PARAMETERS

In an industrial process it is often necessary to monitor and control the successive steps. As is mostly the case in
chemical processes, the methods used for these controls are rather long. It becomes more advantageous to develop alternative methods such as spectroscopic methods, which are more rapid than classical ones, to measure both physical and chemical parameters.

Spectroscopic methods are very interesting when real-time-based measurements are necessary. IR can provide information on raw materials and on the corresponding final products, but additionally it provides an excellent way for process control.

These measurements are advantageous only when it is possible thereafter to control the measured parameter with the aim of improving the efficiency of the process. These parameters are generally physical or chemical.

3.1 Chemical Parameters

It is evident that foods and pharmaceutical products should be carefully analyzed for security reasons and, for these products, the concentration of sample components is extremely important for health and toxicological reasons.

Several parameters can be measured: (i) IR analysis can in many cases be used to analyze the degree of contamination of a sample, hence its purity. In the food industry these aspects are not only important but are moreover imposed by regulations and by the existing quality standards requirements which are very constraining in several countries; (ii) chemical characteristics, the identification of functional groups (OH, NH₂, COOH, etc.) or identification of constituents (sugars, alcohols, fatty acids, proteins, etc.).

The type of calibration is defined as a function of the products to be analyzed. IR spectrophotometers will need to have the species “introduced” in all possible matrices that might occur in a particular reaction/process. It is however possible to select a wavelength and to use the Beer–Lambert law. When several absorption bands recover, it is still possible to select a specific wavelength by using powerful multidimensional data analysis.

In complex mixtures, powerful mathematical tools, such as PLS or PCR, are used for the quantification of a particular constituent. These mathematical treatments can be applied to a part of the spectrum or to the whole spectrum.

It should not be forgotten that the accuracy of the prediction is dependent on the accuracy of the reference method. It should also be remembered that spectroscopic calibration methods demand as much time and resources as a chemical method would demand in order to guarantee their traceability. The advantages of using such methods are their relatively low costs, their accuracy and their speed.

3.2 Physical Parameters

In addition to the concentration values of sample constituents, physicochemical parameters in fluids can be monitored by IR or NIR. These vibrational spectroscopic techniques are very sensitive to matrix effects such as those existing in the presence of hydrogen bonds. Among the physical parameters most currently measured are:

- Viscosity, which is influenced by the number of hydrogen bonds in the samples. It is therefore possible to measure viscosity by IR spectroscopy.
- Density, since it directly influences the transmission of incident light.
- Color, which can be obtained by an ultraviolet/visible (UV/VIS) spectrophotometer; the advantage of FTIR lies in the possibility of verifying that the color is really given by the supposed constituents of the samples.
- Distillation temperature, or practical parameters such as the octane number in gasoline, are closely related to the sample composition and can be easily derived from the IR spectra using appropriate mathematical models.

4 APPLICATIONS OF DIRECT QUANTITATIVE INFRARED SPECTROSCOPY

4.1 Infrared Spectroscopy in Food Analysis

To date, the ease of utilization of spectroscopic methods such as NIR, MIR, UV/VIS and also Raman or nuclear magnetic resonance (NMR) is such that they can be used in routine analysis in quality management and control of food industry production.

NIR is the most commonly used spectroscopic method in the food industry for the quantification of major biochemical constituents. Its success is primarily due to its simplicity and its rapidity. Analytical results can be obtained in few seconds, even if the samples are opaque to IR radiation, such as solid substrates.

The first trials were performed in 1960 under the direction of the United States Department of Agriculture (USDA). A series of investigations were undertaken in order to develop physicochemical methods for rapid characterization of foodstuffs. Norris(28) et al. rapidly assessed the advantage of using the NIR range: NIR is the only region suitable for the diffused reflection technique, which does not require dilution of samples in an optically inactive substance like potassium bromide. In 1962, he developed the first apparatus for the quantification of water by NIR spectroscopy.(28) These trials showed that
constituents such as proteins, lipids and starch hindered the measurement of water content. This problem was alleviated with the application of multilinear regression to spectral data. This not only improved the precision of the quantification of water but also allowed the quantification of other constituents.

From 1970, numerous types of apparatus were specifically devised for specific analytical applications and were commercialized. These devices were spectrophotometers with interferential optical filters and were coupled to microcomputers. The filter-based NIR instruments were able to perform few measurements at some specific wavelengths only. Nowadays, the most sophisticated spectrophotometers are built with interferometers and make use of Fourier transform signal processing.

The field of application of NIR spectroscopy is very wide: it covers the quantification of major constituents such as water, proteins, lipids and sugars in almost every foodstuff.\(^2\,3\)

The incorporation of the Fourier transform technique into MIR spectrometers\(^29\) and the advent of new and easy to use techniques\(^30\) such as ATR, photoacoustic spectrometry (PAS), diffused reflectance infrared Fourier transform (DRIFT) has largely contributed to the progress of IR-based analytical methods. In 1991, several workers showed that ATR was potentially a powerful tool for the study of food products.\(^31\text{-}33\) With the application of Fourier transforms, it was possible to obtain MIR spectra by diffused reflection. Fuller and Griffiths\(^34\) and Depecker et al.\(^31\) demonstrated the advantages of the diffused reflection technique for the study of biological samples.

The use of MIR spectroscopy for the analysis of foodstuffs is still restricted. Few example applications have been described; Renard et al.\(^35\) used MIR for the analysis of cereals and related products. Other applications for the analysis of milk and dairy products have been proposed.\(^56\)

We will now describe the use of spectroscopy for direct spectroscopic quantitative analysis in the study of lipids, carbohydrates and proteins. We will then show the possible applications of IR spectroscopy to the study of enzymatic reactions. Finally, examples of quantification through FTIR spectrometry coupled to other analytical techniques such as FA, vapor generation, gas chromatography (GC), microwave-assisted vapor-generation, and sequential injection analysis (SIA) will be reviewed (Figures 2–4).

### 4.1.1 Lipids

The rapid control of the quality of lipids is a major preoccupation in the food industry. NIR has long been used for this purpose. Recent developments in MIR...
spectroscopy, such as the advent of the ATR method, which has solved the water absorption problem, have made its use in food analysis easier.

4.1.1.1 Measurement of the Unsaturation Degree of Lipids Holman and Edmondson\(^{(37)}\) have shown that the increase or decrease in the intensities of bands in the 2190–2150 nm region is related to the unsaturation degree of lipids. They attributed the bands at 1180, 1680, 2150 and 2190 nm to the group \(-\text{C}=\text{H} \text{ "cis"}\). The bands at 1680 and 1180 nm are the first and second harmonics respectively. They also noticed that NIR did not allow the identification of \(-\text{C}=\text{H} \text{ "trans"}\) in lipids. In 1959, Holman estimated the unsaturation degree of lipids by NIR, MIR and by the iodine index method. Results obtained by MIR and by the classical chemical method were similar. However, since trans-unsaturation could not be detected by NIR, the unsaturation degree was systematically underestimated with NIR. Fenton and Crisler\(^{(38)}\) developed a NIR-based analytical method in order to determine the cis-unsaturation degree in free fatty acids from refined oils. Murray\(^{(39)}\) also showed that the absorption bands at 2150 nm and 2190 nm indicated the existence of a cis-double bond in free fatty acids.

Wheeler\(^{(40)}\) has intensively investigated the structural analysis of lipids through their MIR absorption spectra. MIR is now used routinely for the determination of cis- and trans-fatty acids in oils and fats and has been adopted as an official routine method by the American Oil Society (AOCS) and the International Union of Pure and Applied Chemistry (IUPAC).

Ahlers et al.\(^{(41)}\) have studied the unsaturation degree of pure and sterified free fatty acids. Their investigation was based on the measurement of the intensities of absorption bands at 3015 and 967 cm\(^{-1}\), which were attributed to elongation of cis \(-\text{C}=\text{H} \text{ groups and } -\text{CH}=\text{CH}-\text{ trans-deformation respectively. The intensity of these two bands increases with the unsaturation degree. The band at 3010 cm}^{-1}\) also often determined the unsaturation degree.

**Figure 3** Manifolds employed for vapor generation FTIR analysis. (a) Single-channel flow manifold with a nitrogen carrier flow. (b) Closed FIA manifold.

**Figure 4** Manifold employed for microwave-assisted vapor-generation FTIR spectrometry: \(l_1 = 88\) cm, \(l_2 = 100\) cm, \(l_3 = 60\) cm.
degree and was attributed to valence vibration of the $\equiv C\ H$ cis-group. Kochhar and Matsui\(^{[42]}\) have performed the determination of free trans-fatty acid content by a transmission method; the band characteristic of C–H in a trans double bond is located at 965 cm$^{-1}$.

O’Connor\(^{[43]}\) has conducted detailed studies in order to differentiate between the cis- and trans-isomers that were associated with unsaturation.

Arnold and Hartung\(^{[44]}\) have determined the unsaturation degree of 25 different oils in the 3700–3200 cm$^{-1}$ region. The unsaturation degree is proportional to the quotient of the intensity of bands at 3015 cm$^{-1}$ and 2860 cm$^{-1}$. These bands are attributed to the symmetric valence vibration of the $\equiv C\ H_2$– group.

Anderson et al.\(^{[45]}\) have developed a spectroscopic method for the precise determination of the unsaturation degree in butters and oils. They validated the results found from their method by comparing them with those obtained by the iodine index method. The correlation between IR absorbance and iodine index was verified for butter and mono-hydrogenated oils. Significant correlation coefficients ($r = 0.97$) were obtained (Ahmed and Helal\(^{[40]}\)) between absorbance at 1015 cm$^{-1}$ (due to olefin cis–trans isomerism during hydrogenation) and the iodine index method.

With the use of ATR, Belton et al.\(^{[47]}\) have quantified trans-unsaturated fatty acids in oils and lipids. The characteristic trans $\equiv C\ H$ band determined by Belton was located at 976 cm$^{-1}$.

**4.1.1.2 Lipids Determination**

NIR has long been used as a standard routine method for quantification of lipids in foods and in particular in milk and related compounds.\(^{[48–50]}\)

Sato and Kawano\(^{[51]}\) showed that characteristic bands of lipids in milk are featured at 1164, 1660, 2144 and 2176 nm. These bands are attributed to cis-unsaturations in the fatty acids existing in milk.

Lipids have been quantified by NIR in a great variety of substrates: meat products,\(^{[52,53]}\) cereals\(^{[54]}\) and oleaginous seeds.\(^{[55–57]}\)

In 1986, Murray\(^{[39]}\) showed, from a collection of NIR spectra of free fatty acids, that the only difference that can be noticed was in the absorption bands related to the number of CH$_2$ groups.

MIR absorption bands have been used for the quantification of lipids in milk.\(^{[58,59]}\)

With the use of devices equipped with interferential filters, the quantification of lipids by measuring the absorption at 1754 cm$^{-1}$ (characteristic of ester groups) is possible. Since there are on average three ester links in most molecules, this technique is in fact a mean for counting molecules. If the mean molecular weight is constant, the absorption measurements at 1754 cm$^{-1}$ allow the precise assessment of the amount of fats. However, milks show great variations in their fatty acid composition according to their origin and the period of sample collection. In order to overcome this problem, a second filter can be used. This filter permits measurements between 2940 and 2860 cm$^{-1}$ and allows the determination of the average size of fatty acid molecules by measuring the number of C–H bonds.

**4.1.2 Quantitative Analysis of Carbohydrates**

Both NIR and MIR have been employed for carbohydrate determination in foods.

**4.1.2.1 Near Infrared Spectroscopy of Carbohydrates**

Numerous workers have used NIR for the analysis of sugar contents in foodstuffs. McClure et al.\(^{[60]}\) have directly measured total reducing sugars in tobacco leaves. Giangiacomo et al.\(^{[61]}\) predicted, with very good precision, the fructose, glucose and sucrose contents of apple juices or of reconstituted mixtures of carbohydrates. Lanza and Li\(^{[62]}\) were able to predict total sugar content in fruit juices; Osborne et al.\(^{[63]}\) measured sugars in biscuits; Kaffka and Jeszenszky\(^{[65]}\) determined sugars in wines; Baker and Norris\(^{[66]}\) determined the sugar content in cereals and other foodstuffs;\(^{[67]}\) Robert et al.\(^{[68]}\) analyzed apples, and Ootaka\(^{[69]}\) studied tomatoes. Rambla et al.\(^{[70]}\) determined glucose, fructose, sucrose and total sugar contents in fruit juices by means of the PLS data treatment of NIR measurements.

Baker\(^{[77]}\) quantified starch content and total soluble sugars in fast foods. Bertrand et al.\(^{[77]}\) measured total parietal constituents contents in wheat products, including various types of semolina.

NIR can be used to determine the state of starch degradation but this characterization is not supported by a molecular approach. Osborne and Douglas\(^{[71]}\) have applied NIR spectroscopy to the prediction of this parameter. In their investigations, they used commercial flour with different degrees of starch degradation. The procedure is useful for the classification of flour according to the extent of starch degradation.

The potential application of NIR spectroscopy in the sugar industry has been assessed. These studies were undertaken on sugarcane juices\(^{[72,73]}\) and on beetroot juices.\(^{[74,75]}\) Studies performed using an InfraAlyser 450 equipped with 20 filters have shown that it is possible to predict with good precision the sucrose content, as well as the Brix index and humidity, from diluted raw juices. However, these studies were performed on a limited number of samples. In 1989, Ames et al.\(^{[78]}\) collected and analyzed up to about 600 NIR spectra of raw sugarcane juices that were collected from several centers in Australia in 1987. The InfraAlyser 500 allowed investigation in the
whole range covering 1100–2500 nm. The results obtained appear to be satisfactory according to the standards of routine analysis in industrial processes. However, a systematic deviation between the polarimetric values and sugar contents predicted by NIR spectroscopy during particular periods in the sugarcane collection has been noticed.

Altenburg and Chou\cite{77} proposed working at 882.6 nm in NIR to determine sugar contents in raw sugarcane juices with a NIR-polarimeter. This work on IR spectroscopy were encouraged by the International Commission for the Uniform Methods of Sugar Analysis (ICUMSA).\cite{78}

4.1.2.2 Mid-infrared Spectroscopy of Carbohydrates

MIR spectroscopy has been used since 1950 for the study of carbohydrates. Structural analysis of carbohydrates from their MIR spectra has been thoroughly investigated.\cite{79,80,81,82} Apart from starch, the sugars that are of most interest to the food industry are sucrose, glucose and fructose.

Barker et al.\cite{80} have systematically studied aqueous solutions of carbohydrates by MIR in an attempt to identify bands that are characteristic of sugars in aqueous solutions.

In nonaqueous solvents, there exist IR spectroscopy studies that were carried out on model molecules that featured patterns characteristic of carbohydrates.\cite{82} These investigations essentially focused on the O–H absorption band in the 3700–3300 cm\(^{-1}\) region, with the aim of determining sucrose chelation in nonaqueous solutions.

Only a few works are concerned with MIR spectroscopy for direct sugar quantitative determinations. Dupuy et al.\cite{83} have quantified sugars in fruit juices and syrups but they suggested that the results obtained with diffused reflectance did not meet the standards required for a possible use in quality control, particularly for quantitative analysis.\cite{84}

Cadet et al.\cite{85} were the only team to investigate the use of MIR spectroscopy for the study of sugarcane juices. Their work was motivated by the fact that the price of sugarcane is estimated by its sucrose content. Not only is the method used to determine sucrose content in sugarcane fundamental, but also the delay and costs of the analyses are important. Polarimetry and high-performance liquid chromatography (HPLC) are the most commonly used techniques to measure sucrose content in sugarcane. However, it has been shown that polarimetric measurements underestimate sugar content. Measurements by HPLC are not precise enough and the results are not easily reproducible for routine analysis and need a preliminary sample clarification before the analysis is carried out.

MIR ATR can be used to study samples that are difficult to analyze. This is the case for raw sugarcane juice, which is completely opaque.

PCA and PCR were subsequently used to assess and describe MIR spectral data of crude sugarcane juices. The method was validated on a panel of 1267 samples representative of a sugarcane collection.

A peak at 997 cm\(^{-1}\) was the most important for the quantification of sucrose. After PCR, the first introduced component gave a correlation coefficient value towards sucrose equal to 0.878 and, with the second introduced component, this value reached 0.949. The bias and the standard deviation of the differences between the reference value and the predicted value are 0.041 g/100 mL and 0.289 g/100 mL respectively. When compared to values obtained between the reference value and direct polarimetric values (−0.163 and 0.087 g mL\(^{-1}\)) these values show that the proposed method yields values that are very close to real ones. This method, which uses MIR ATR, allows direct measurements of sucrose content in raw juices and hence is more advantageous for routine analysis and industrial processes than the polarimetric method. Furthermore, the proposed method eliminates costs linked to consumption of the polluting agent lead acetate, and eliminates the lengthy filtration phase. The whole procedure, from raw sugar analysis to prediction of sucrose content, needs only about 25 s for each sample.

Vonach et al.\cite{85} used MIR transmission spectrometry for the direct determination of glucose in human blood.

4.1.3 Quantitative Analysis of Proteins

Proteins are macromolecular structures constituted of polypeptide chains of amino acids that are linked by peptide bonds. It is common to distinguish the different structure and organization of proteins following the nature and the repetitive character of the interactions that exist within the macromolecules.

The primary structure of a protein is defined as its sequence of amino acids.

The secondary structure of a protein is defined by the spatial arrangement of the amino acids in the polypeptide chain. A limited number of particularly favorable spatial configurations are adopted by atoms of each amino acid in a polypeptide chain, which folds to give rise to the well-known secondary structures: the alpha helix and beta strands, as well as less regularly defined structures like turns, loops and coils.

The tertiary structure of a protein is the spatial arrangement of the whole polypeptide chain and arises from the packing of different folding regions owing to interactions between the side chains of the constituent amino acids.
The quaternary structure of proteins describes the arrangement of several polypeptide chains that are associated to form a supramolecular structure.

MIR spectroscopy has been widely used for the determination of polypeptides and protein secondary structures. Miyazawa and Blout carried out normal coordinate calculations on model compounds, which showed three strong IR bands of proteins, called amide I, II and III. The most representative spectral region is that between 1600 and 1700 cm\(^{-1}\), which is characteristic of amide I.

### 4.1.3.1 Predicting Protein Secondary Structures

The secondary structure of a protein is difficult to investigate by physical analytical methods. MIR spectroscopy provides a gateway for studying secondary structures, in particular for quantifying the relative proportioning of alpha helix, beta sheets, turns, etc.

The position of the amide I and II absorption bands depends on the dihedral angles in the peptide units, and hence on the type of periodical structures existing in the investigated protein molecule. Several methods for predicting secondary structures in proteins from IR spectra have been subsequently developed.

Two major methods have been described:

- Methods based on direct analysis of spectra, either by deconvolution, or by calculation of the second derivative.
- Methods that use calibration from a collection of spectra of proteins of known structures.

In 1990, Dousseau and Pézolet showed that vibrational spectroscopy in the MIR region can be used to determine with a good precision the secondary structure of proteins. The results obtained can be favorably compared to those obtained by circular dichroism or by Raman spectroscopy.

The proposed method consists of the following steps: subtraction of the spectrum of water, baseline correction and normalization of the spectra, and application of PLS to the corrected spectra – for the prediction of secondary structures.

FTIR spectroscopic studies on membrane proteins were at first mainly of a qualitative nature. Recent developments provide quantitative information as well. For example, PLS FTIR predictions of the secondary structure of the following membrane proteins have been performed: Ca-ATPase, cytochrome oxidase, glucose transporter, rhodopsin, porin, etc. Methods used for quantitative analysis are either based on curve-fitting techniques or pattern recognition.

### 4.1.3.2 Quantitative Analysis of Proteins

The quantitative analysis of proteins by NIR spectroscopy is an alternative to the classical Kjeldahl chemical method and is, as a matter of fact, of great economic importance.

The quantification of proteins in cereals is by far the most important application of NIR spectroscopy. Proteins present several characteristic absorption bands in NIR. The most intense band is located in the 2170 and 2180 nm region. This band is attributed to a combination of the amide I band with that of the amide III band. Quantification of proteins by NIR is as precise as quantification with the Kjeldahl method.

In MIR, a method for the quantitative measurement of \(\alpha\)-amino groups from amino acids, peptides and proteins has been proposed by Cadet. The spectral region where the characteristic absorption bands of such groups are located ranges between 1200 cm\(^{-1}\) and 1900 cm\(^{-1}\). Water shows a major absorption band in this region (1500–1700 cm\(^{-1}\)). This superimposes on the amide I and II bands.

The standard deviation for each and every wavelength, calculated for all the spectra of the calibration set, shows the existence of two absorption bands in the 1500–1900 cm\(^{-1}\) region. This means that the observed variations in this zone are not only due to water but are also due to two peaks centered at 1650 cm\(^{-1}\) and 1540 cm\(^{-1}\) (with a trough at 1600 cm\(^{-1}\)) that are characteristic of proteins.

Good predictions were obtained; the mean and standard deviation associated with the predicted concentrations of \(\alpha\)-NH\(_2\) (protein) content were 0 g mL\(^{-1}\) and 0.12 g mL\(^{-1}\) respectively. Hence, it has been clearly established that it is possible to determine the \(\alpha\)-NH\(_2\) content of foods from their MIR spectra.

### 4.2 The Use of Infrared Spectroscopy in Enzymatic Analysis

Enzymatic studies are often carried out in two different ways: (i) by the determination of the amount of a product or a reagent after reaction through a generally lengthy chemical method or, (ii) by using coupled enzymatic assays, so that a chromophore, like NAD(P), was oxidized or reduced and was finally titrated. This second method is more often used for quantitative analysis through enzymatic reactions that generally do not give chromophoric or fluorescent products directly. However, the use of other enzymes in coupled assays implies a good understanding of their kinetics and can make some studies difficult. As for example is the variation of the activity of an enzyme according to pH. So, for the assay of enzymes with products and reagents that have no absorption in the UV/VIS region, it may be interesting to avoid coupled enzymatic assays and to proceed in a single step.

Recent developments in analytical IR spectroscopy, and particularly the possibility of connecting computers...
to spectrophotometers, make this technique easier and give it new scope. Cadet et al.\(^{(98)}\) first investigated the potential of MIR spectroscopy combined with multidimensional statistical analysis, using an ATR cell to allow a one-step enzymatic assay. In this way, they proposed an alternate method for enzyme study. Hydrolytic activity of β-fructosidase, with sucrose as substrate, was monitored. Familiar progress curves can be obtained by quantification of the remaining substrate, and enzymatic studies of the kinetic properties of the enzyme become possible. The proposed method offers an alternate analytical procedure for enzyme studies. It also allows the identification of structural changes in a compound during a reaction. Furthermore, the study of the enzyme can be carried out directly without resorting to coupled assays. The authors suggested that the method could be extended to any enzyme, with appropriate calibration.

Schindler et al.\(^{(99)}\) proposed an automated method for the determination of amyloglucosidase (glucan 1,4-α-glucosidase) activity in aqueous solutions. Amyloglucosidase is produced from Aspergillus niger by submerged fermentation and is frequently used in industry, e.g. for starch liquefaction in food and pharmaceutical industries.\(^{(100)}\) The method is based on the direct FTIR spectrometric monitoring of starch hydrolysis catalyzed by amyloglucosidase. It is shown that spectral changes caused by the enzyme activity can be followed by the study of the MIR spectra, hence eliminating the need for additional consecutive reaction steps which are normally required to derive a reaction product detectable by conventional techniques such as UV/VIS spectroscopy or electrochemistry. Unspecific background absorption was eliminated by calculation of a difference spectrum between nonreacted starch and the reaction mixture. To guarantee optimum handling of the viscous starch solution and to obtain high sensitivity, a flow injection analysis (FIA) system using the merging zone approach and the stopped-flow technique was developed. Using a stopped-flow time of 5 min and a 55 g L\(^{-1}\) starch substrate solution, linear calibration curves from 50 to 2000 U\(^{1}\) (830–33 300 nkat L\(^{-1}\)) were obtained. The coupling of a FTIR spectrometer with a flow system capable of performing chemical reactions in an automated, repeatable and reproducible way was proved to enhance the detection power of the FTIR instrument. By using this approach, a parameter, which is not accessible by a single FTIR measurement, could be successfully determined. Furthermore, this coupling has demonstrated new possibilities for the application of MIR FTIR spectrometry for remote process monitoring and process control and has been applied for the study of other enzymes.\(^{(75,101)}\)

### 5 APPLICATIONS OF FOURIER TRANSFORM INFRARED ANALYSIS COUPLED WITH OTHER ANALYTICAL METHODS

FTIR spectroscopy has been traditionally used to obtain qualitative information of organic sample. But recently it has been demonstrated that FTIR spectroscopy is also an excellent tool to obtain accurate quantitative results from spectra obtained in solid, liquid or gaseous states, in spite of the general problems encountered when using traditional systems of IR measurements.\(^{(102–104)}\)

Table 6 provides a picture of the main drawbacks of traditional systems of IR spectra acquisition and the different strategies that can be adapted to solve all these problems.

Among the problems which remain for general applicability of FTIR spectroscopy for quantitative analysis are the solvent and window material transparencies.\(^{(105)}\) These are still the main reasons for a limited development in this field. For the analysis of aqueous samples by FTIR, it is necessary to use adequate transmittance or reflectance cells with water-resistant windows. The use of transmittance measurements requires very small path lengths, of the order of 25 μm, due to the strong water absorption, and the use of ATR cells involves poor sensitivity.

The vapor or gaseous state is very useful for carrying out determinations by FTIR. This is due to the high transparency of gases, the low background obtained for this kind of systems and the possibility of using multiple pass gas cells which can provide good sensitivity.\(^{(106,107)}\) For these reasons, FTIR spectrometry has been extensively used for detection in GC\(^{(108–110)}\) and also in combination with sample pyrolysis.\(^{(111–113)}\) More recently, a new strategy for FTIR analysis based on vapor generation from small injected volumes of liquid samples has been

developed. This technique was applied to the quality control of solvent additives, paint analysis, gasoline component, and to the determination of alcohol in aqueous samples like alcoholic beverages and in blood.

Many examples of on-line determination exist. Most of them deal with the chemistry of synthesis and with the food and pharmaceutical fields.

In recent years, FIA methodology has been incorporated into most branches of analytical chemistry. The second edition of Ruzicka and Hansen’s book included 588 references for the use of FIA in UV/VIS determinations, 123 in atomic absorption spectroscopy, 72 in spectrofluorimetry and only 4 in FIA/IR. These values grew up during the past decade. Below, some examples of applications are given.

FTIR has a better selectivity than UV/VIS spectrometry and provides an excellent tool for the determination of mixtures of compounds. On the other hand, in the last few years, FIA/FTIR has been demonstrated to be a synergistic combination highly appropriate for the quality control of drugs.

In general, the analytical procedures developed for IR determination require the use of organic solvents, and frequently chlorinated solvents, such as CCl₄, CHCl₃ and CH₂Cl₂, are those that provide the best transparency in the IR range and the lowest limits of detection. However, these reagents are highly toxic and efforts must be made to replace these reagents or to reduce drastically the amount of solvents employed through the automation of measurements and the development of on-line recycling techniques. The FIA/FTIR methodology offers a fast and simple way for automating the sample and measurement operations and provides a clean analytical method.

FIA offers an inexpensive and versatile means for the automation of analytical procedures, and hence it has been incorporated in many different techniques. FTIR spectroscopy is a powerful technique for qualitative and quantitative organic analysis and this has led to the development of a flow injection procedure for use with FTIR analysis.

The use of flow injection in conjunction with IR analysis provides a simple and reproducible way to fill and clean the liquid cells. It also allows (i) the rapid automation of the determination and (ii) a strong reduction in the consumption of reagents and in the production of wastes. The use of FTIR permits an increase in the sensitivity, by accumulating a series of scans in the stopped-flow mode, the continuous monitoring of the baseline of the spectra and the accurate determination of the maximum of absorbance bands.

The recent development of FA procedures in the field of IR spectrometry has solved some of the many drawbacks of quantitative determination using this technique: (i) repeatability and accuracy of the determinations have been improved; (ii) the possibility of direct analysis of real samples has been enhanced; (iii) easy and fast methods for the quantitative control of several compounds in the same sample have been provided and (iv) the sensitivity of FTIR determination has been increased by means of on-line coupling with concentration techniques.

The use of FA FTIR derivative spectrometry permits additionally the direct determination of compounds in real samples, without requiring previous separation or clean-up procedures and without problems in establishing the baseline (Figures 5–7).

5.1 Fourier Transform Infrared Determination in Pharmaceuticals

IR spectrometry provides a useful way to identify drugs. However, traditional techniques employed to obtain the IR spectra, such as alkali halide disks, mulls and thin films, are not adequate either for quantitative analysis, or for the use of transmittance spectra. For this reason, UV spectroscopy was for a long time, and is still currently, employed in the analysis of pharmaceuticals rather than IR. The use of flow cells for handling appropriate solvents and with well-selected spacers and windows opens the possibility of carrying out quantitative IR determinations of drugs, especially for the development of automated procedures based on FIA. Ibuprofen is a nonsteroidal anti-inflammatory analgesic that can be quantified by the combination of FIA/FTIR (Figure 8).

FIA has been successfully used for the determination of acetylsalicylic acid, caffeine, dimenhydrinates and paracetamol.

Propyphenazone and caffeine are important analgesic and stimulant drugs respectively, which are commonly used and combined in pharmaceutical formulations. A procedure has been proposed for the simultaneous FTIR determination of propyphenazone and caffeine in commercial pharmaceutical formulations. The method involves the dissolution of the active principles in CHCl₃, followed by filtration of the sample solution, to remove the other molecules than “active principles”. Propyphenazone is determined by absorbance measurements at 1595 cm⁻¹, using a baseline established between 2000 and 890 cm⁻¹, and caffeine by using the first derivative values at 1712 cm⁻¹, using propyphenazone and caffeine standards for external calibration. The method was applied in both stopped-flow and flow injection modes, providing precise and accurate results for the quantitative analysis of samples (Figure 9).
Bouhsain et al.\textsuperscript{[120]} proposed the simultaneous determination of paracetamol, acetylsalicylic acid and caffeine. The simultaneous determination of these three active principles can be performed by using multivariate calibration. Various numerical methods were proposed in combination with molecular spectroscopy, such as Kalman filtering and UV data,\textsuperscript{[141]} multiple linear regression of the NIR reflectance data\textsuperscript{[142]} and multivariate programs applied to UV measurement such as multicomponent simplex analysis and multic\textsuperscript{[143]} iterative.

QUANTITATIVE ANALYSIS, INFRARED

Figure 7 Manifold employed for vapor generation FTIR determination of carbonate in waters. Volumes and flow values are those corresponding to the best conditions of analysis. The porous silicone rubber tube has a 0.8 mm internal diameter, a 1.6 mm external diameter and a length of 60 cm.

The determination of aromatic hydrocarbons in naphthas and motor gasoline is necessary in several areas of the petroleum, petrochemical and related industries. Detailed information on the aromatic composition of fuel materials, intermediates and commercial products is required for process development and quality control programmes. Legislation in several countries limits the upper concentration of some hydrocarbons in commercial gasoline.

Figure 8 Manifold employed for the FIA/FTIR determination of ketoprofen and on-line solvent recycling. L₁ = 55 cm, L₂ = 78 cm and L₃ = 43 cm.

target transformation factor, step regression and PLS regression. The latter also developed a PLS/FTIR procedure for the fast and accurate simultaneous determination of paracetamol, acetylsalicylic acid and caffeine in commercial pharmaceutical formulations. This reduced preliminary sample treatment to the leaching of compounds to be determined from the pharmaceutical formulations with a 10% v/v solution of ethanol in dichloromethane in an ultrasonic water bath for 20 min, and providing the direct FTIR determination by using a simple matrix calibration including only eight standards.

Garrigues et al. have developed a method for the determination of ibuprofen in pharmaceuticals by FTIR, using the carbonyl band, which the compound presents at 1710 cm⁻¹ in carbon tetrachloride solution.

5.2 Fourier Transform Infrared Determination in Petroleum Products

The determination of aromatic hydrocarbons in naphthas and motor gasoline is necessary in several areas of the petroleum, petrochemical and related industries. Detailed information on the aromatic composition of fuel materials, intermediates and commercial products is required for process development and quality control programmes. Legislation in several countries limits the upper concentration of some hydrocarbons in commercial gasoline.

Figure 9 Manifold employed for the clean simultaneous FTIR determination of propyphenazone and caffeine.
FTIR spectrometric techniques are known to provide a rapid means for the direct determination of aromatic compounds. Gallignani et al. proposed a FTIR procedure for the automated determination of benzene in gasoline, based on the use of FIA. The method permits the direct determination of benzene without any pretreatment of samples, with a limit of detection of 0.002% (v/v). Results found by direct analysis agree well with those obtained by off-line and on-line standard addition methods. A rapid quality control procedure was developed, based on the on-line injection of 1:10 diluted gasoline samples into a carrier stream of a 0.5% (v/v) solution of benzene in hexane; the baseline corresponds to the upper limit tolerated by the European Economic Community’s law for gasoline. On the other hand, the American Society for Testing and Materials (ASTM) has proposed the IR batch determination of benzene in motor and aviation gasoline. (149)

Methyl tert-butyl ether is an antiknock agent commonly employed in unleaded gasoline. The additive is frequently determined by GC in gasoline, in synthetics products and in estuarine waters and sediments. A NIR method has been applied to the direct measurement of methyl tert-butyl ether in gasoline with an associated standard error of 0.1% (v/v) by using the second overtone NIR region. (150)

Daton et al. used a batch method for the determination of this compound in gasoline based on direct absorbance measurement at 851 cm⁻¹ by using ATR. They obtained a relative standard deviation that ranged between 1 and 1.6% for the analysis of samples containing 7% (v/v) of methyl tert-butyl ether.

De la Guardia et al. proposed a method for the flow injection FTIR spectrometric determination of methyl tert-butyl ether in unleaded gasoline. The method is based on the use of first-order derivative measurements in a flow system. The recovery of methyl tert-butyl ether in spiked natural samples varies from 98.2 to 102% and the relative standard deviation was 0.6% for samples containing 0.8% (v/v) methyl tert-butyl ether. Results obtained in the analysis of commercial gasoline samples compare well with those found by GC.

The determination of organic compounds in complex matrices suffers from serious limitations owing to the overlapping of absorbance bands, which prevents direct determinations of a series of compounds and causes strong matrix interference.

The use of derivatives techniques in spectrometry has opened up new possibilities for the resolution of mixtures and compensation for matrix interference. (152–154,131)

Petrol is a complex mixture of volatile flammable liquid hydrocarbons containing hundreds of different natural components and some additives.

Gallignani et al. proposed the simultaneous FA FTIR determination of benzene, toluene and methyl tert-butyl ether.

Kerosene is an important fuel for practical purposes. Under different names or with slightly different characteristics, refined kerosene is the selected fuel for civil and military use in jet-fuel turbine aircraft. Therefore it is an important task to assure the kerosene quality. The main kerosene physicochemical characteristics are covered by the British Ministry of Defence specification (155) and/or the ASTM guides. (156) Both of them comprise a minimum of 26 tests to be carried out by refinery laboratories and/or external surveillance companies.

Several aircraft fuel quality properties like density, freezing point, flash point, aromatic content, initial boiling point, final boiling point and viscosity have been predicted from the FTIR spectra in the range 4000 to 600 cm⁻¹, using multivariate techniques. Multiple linear regression, PCR and PLS models have been tested. FTIR/PLS repeatability and reproducibility values fall well within the ASTM ranges and the standard error of prediction values is good. Sample manipulation was improved by using a stopped-flow system. (5)

5.3 Fourier Transform Infrared Determination of Industrial Products

Ethanol and also amylene are added to analytical reagent-grade chloroform as stabilizers in order to avoid the decomposition of this chlorinated solvent and the formation of phosgene. (157) The determination of ethanol in chloroform can be carried out by chromatography. However, IR spectrometry, in the near range, offers exciting possibilities for this type of analysis due to the transparency of chloroform and the presence of characteristic bands of ethanol in this region of the spectrum. In the last ten years, a big effort has been made in the development of on-line procedures for process monitoring, based on NIR measurements, generally using a combination of chemometrics and fiber-optic probes. Working at a fixed wavelength or using the stopped-flow approach, it is possible to develop the FIA/NIR procedure for a variety of aqueous and nonaqueous samples. López-Anreus et al. proposed a simple and direct FIA procedure for the determination of the stabilizing agent ethanol in chloroform samples. The procedure is based on the use of an absorbance band of ethanol in the NIR region at 2272 nm, measured in front of a reference sample of chloroform stabilized with amylene. The method developed provides a limit of detection of 0.0045% (v/v) and a dynamic range up to 10% (v/v). The variation coefficient of six independent analyses of a real sample containing approximately 1% (v/v) of ethanol was as low as 0.4%, while the injection frequency can reach 78 samples per hour.
Polymers are present in a large number of manufactured products and the quality of a polymer is established from different parameters: viscosity, end-group analyses, branching percentage, cross-linking degree, degree of crystallinity, density and molecular weight, which are characteristic of each lot.

Polymers have been investigated by MIR using transmission data\(^1\)\(^{161}\) and also using NIR.\(^2\)^\(^{26}\) De la Guardia et al.\(^3\)^\(^{162}\) developed a simple procedure for the determination of some average properties of nonylphenol-ethylene oxide condensates, such as average molecular mass, average degree of condensation, the hydrophilic/lipophilic balance (HLB) and the percentage of ethylene oxide, which are characteristic of this kind of surfactant condensate. The method, based on the existence of a regression between the logarithm of the surfactant properties and the logarithm of the ratio of the peak heights of the bands at 960 and 840 cm\(^{-1}\), is precise and accurate. Variation coefficients as low as 0.9% for HLB, 1% for ethylene oxide percentage and 1.6% for molecular mass were obtained.

For the determination of polymers and composite materials by IR, some of the limitations come from the use of extreme temperature and pressure conditions. However, recent developments, such as that proposed by Hanssen and Snail,\(^4\)^\(^{163}\) who developed a diffuse gold integrating sphere which can support up to 250 °C, and the off-the-shelf bidirectional reflectance accessories with controlled atmosphere, which can be used at 500 °C, offer new possibilities for operating in extreme experimental conditions.

### 5.4 Fourier Transform Infrared Determination of Products of the Paint Industries

Xylol, a solvent commonly used in the paint industry,\(^5\)^\(^{48}\)^\(^{164}\)^\(^{165}\) is a mixture of \(\alpha\)-, \(m\)- and \(p\)-xylene. Garrigues and de la Guardia\(^6\)^\(^{102}\) proposed a series of mathematical models for the FTIR determination of \(\alpha\)-, \(m\)- and \(p\)-xylene in xylol without the need to use absorption cells with a known optical path length. The relative errors found in the analysis of binary mixtures are of the order of 1.4%, and those found for ternary mixtures are lower than 3% in most instances, for samples containing from 10 to 75% m/m of each component. In 1992, the same team proposed a FIA/FTIR method for the determination of xylene. The best limit of detection obtained was 0.01% (v/v). The relative standard deviation was 1% for a sample containing 0.4% of \(\alpha\)-xylene in hexane.

Solvents are necessary in paint formulations in order to improve the solubility of resins and polymers and to improve the fluidity of the final product. Organic solvents traditionally employed in paint manufacture include carbonyl and aromatic compounds. However, the use of water as a paint solvent has always been attractive for reasons of low cost and absence of toxicity risks.\(^7\)^\(^{121}\) Water-borne paints need a minimum application temperature of 5 °C adequate film formation and, because of that, atmospheric conditions can delay its drying time. For this reason, these paints need the addition of a co-solvent at low concentrations; the butylglycol being one of the most commonly employed.\(^8\)^\(^{166}\)

The analysis of solvents employed in paint industry is usually carried out by GC.\(^9\)^\(^{167}\)^\(^{168}\) However, this procedure is slow and time-consuming and not very appropriate for the direct analysis of aqueous samples. The use of FTIR allows the direct determination of butylglycol in water-borne paint solvents.\(^10\) The method is based on the injection of 2 μL of untreated paint solvent into an electrically heated Pyrex glass reactor in which the sample is vaporized at 150 °C. The vapor phase generated is transported by means of a nitrogen carrier flow of 400 ml min\(^{-1}\) into an IR multiple pass gas cell and the spectrum in the MIR is recorded between 2500 and 600 cm\(^{-1}\) as a function of time. Data found for samples are interpolated in two calibration curves obtained by injecting different volumes of pure butylglycol and pure water. The measurement of the area of the flow injection recording obtained from the absorbance of the transient signals in the range 1137–1131 or 1071–1065 cm\(^{-1}\) for butylglycol and 1660–1640 cm\(^{-1}\) for water allows the direct determination of these two compounds in the same sample. The method provided relative standard deviation values around 1%, a limit of detection of the order of 2.7–4.5 ng, recovery percentage values from 96 to 104% and a sampling frequency of 65 h\(^{-1}\).

Paint solvents generally contain aromatic and carbonyl compounds with a high volatility. In this sense, acetone is nowadays one of the most important solvents in the paint industry, owing to its high solvent power for a wide range of resins and its economic price. The combination between alcohols and acetone, in different proportions, improves its solvent power and, because of that, acetone and isopropanol mixtures are commonly used in nitrocellulose paint formulations.\(^10\)^\(^{165}\) Vapor generation FTIR provides a way for direct determination of acetone and isopropanol in nitrocellulose paints. Spectra were recorded between 2000 and 500 cm\(^{-1}\). Data found for samples were interpolated in two calibration curves obtained by injecting different volumes of pure acetone and isopropanol. The measurement of the height and area of the flow injection recording obtained from the absorbance of the transient signals in the range of 1743–1737 cm\(^{-1}\) and 956–950 cm\(^{-1}\) allowed the direct quantification of the solvents. The limit of detection of the method was of the order of 0.5–3.9 ng, with a relative standard deviation from 0.09 to 2.8%. The solvent composition in a nitrocellulose paint can be determined by the aforementioned procedure after a...
simple treatment consisting of sample dilution with CCl₄ followed by centrifugation at 4000 rpm for five minutes.⁷

A method has been developed for the direct simultaneous determination of o-, m- and p-xylene in xyol by FTIR. The method is based on the injection of samples, diluted in hexane, into a carrier solution of hexane. The absorbance measurements were carried out at 743, 770 and 796 cm⁻¹. The limit of detection corresponds to 0.03% v/v for o- and m-xylene and to 0.02% v/v for p-xylene, using a 0.13 mm path length micro flow cell.

5.5 Fourier Transform Infrared Determination of Products in the Field of Health

The determination of ethanol in blood is very important, especially in establishing responsibility in traffic accidents. The upper permissible concentration level of ethanol in blood for drivers depends on different national laws; for example, in France, the upper limit is 0.5 g of ethanol per litre of blood. The determination of ethanol in blood is usually carried out, after previous treatment, by headspace GC using a mass-spectrometric detector or a flame ionization detector, or by using a specific instrumentation. Recently, Pérez-Ponce et al.¹¹³ show that this kind of determination can be carried out by FTIR through direct injection of samples in a vaporizer and measurement in the vapor phase, in order to avoid the interference of the sample matrix components. The measurements were made at 1050 cm⁻¹ to increase the selectivity. This band corresponds to the C═O stretching vibration in ethanol and has been demonstrated to be useful for breath analysis.¹⁶⁹ The method is based on the injection of a discrete sample volume of 10 µL into an electrically heated Pyrex glass reactor. The ethanol is vaporized in the reactor at a temperature of 90°C and introduced by means of a N₂ carrier flow inside a long-path IR gas cell. The corresponding FA is recorded as a function of time. With the transient signal obtained in the range 1150–950 cm⁻¹, it is possible to quantify ethanol up to 2 g L⁻¹, with a limit of detection of 0.02 g L⁻¹, and an analysis frequency of 40 samples per hour. This method can be applied to a single drop of finger blood.

IR spectrometry is very useful as a detector in liquid chromatography (LC) to solve complex analyses requiring simultaneous chromatographic and spectrometric discrimination, and provides additional qualitative information not available from conventional LC detector.¹⁷⁰–¹⁷²

FTIR spectrometric detection in LC can be accomplished in two ways: (i) on-line detection via the use of flow cells¹⁷₃,¹⁷₄,²₂₈ and (ii) off-line detection after solvent removal.¹⁷₅,¹⁷₆ The first approach is simpler, but presents limitations regarding excessive absorption caused by the carrier solvents and thus, in general, is less employed. The second approach eliminates the solvent problems but involves the use of expensive interfaces and, because of that, UV/VIS absorbance spectrometry or molecular fluorescence remains one of the most widely used spectrometric detection techniques in LC.¹⁷⁷

LC has been employed for the analysis of oils and greases, providing a good way of determining fatty acids and triglycerides.¹⁷⁸–¹⁸⁰ In some studies, FTIR spectrometry has been employed for the determination of triglycerides, in both normal and reversed-phase,¹⁸¹ esteride triglycerides,¹⁸² free acids and partial glycerides.¹⁸³ Sterols are the main constituents of the unsaponifiable matter and represent an important group of minor components of oils and greases. Stearic acid, cholesterol and cholesteryl palmitate have been separated in less than 14 min by LC coupled with FTIR spectrometry.¹⁸⁴ General detection was carried out at 2868 or 2855 cm⁻¹ and selective detection at 3285 cm⁻¹ for stearic acid and 3526 cm⁻¹ for cholesterol. In all cases, a baseline was established at 3900 cm⁻¹. The method was validated by application to the determination of cholesterol in animal gases and fish oils. Samples that have previously undergone saponification with KOH were extracted with petroleum ether, redissolved in chloroform and the final solution injected into the chromatographic system. The recoveries were 95–99% for samples spiked with cholesterol and 100–102% for samples spiked with cholesteryl palmitate.

Methanol, originally obtained by the destructive distillation of wood, is nowadays usually manufactured from hydrogen and carbon monoxide or carbon dioxide and also by the oxidation of hydrocarbons. These methods of manufacture and the low taxes imposed on this alcohol, as compared with those on ethanol, make methanol a cheap and dangerous substitute for ethanol. The ingestion, inhalation or skin absorption of methanol can lead to anything from headaches to blindness and even death (the latter from ingestion of 100–200 mL). Therefore, (the latter) analytical control in both beverages and cosmetics is necessary. Colorimetry, GC and immersion refractometry are the three methods recommended by the Official Methods of Analysis of the Association of Official Analytical Chemists (AOAC)¹⁸⁵ for methanol determination in beverages. However, all these methods need the previous treatment of samples, which is, in general, tedious and time-consuming. IR spectrometry has been employed in the identification or quantification of methanol in a series of different samples. Open path FTIR can be employed for qualitative monitoring of methanol vapor in the atmosphere.¹⁸₆ Quantitative methods have also been proposed for the NIRS second derivative determination of methanol in synthetic mixtures of methanol, butanol, acetone, methylene chloride and dichloropropane.¹⁸⁷
Similarly, methods were proposed for FTIR determination of mixtures of 2,2-dimethoxypropane, acetone and methanol,\(^\text{188}\) which is especially useful in the simplex optimization for FTIR remote sensing measurement of SF\(_6\), methanol, acetone and 2-butane in synthetic mixtures.\(^\text{189}\)

For the analysis of real samples, optical fiber NIR spectrometry was used for methanol determination in gasoline.\(^\text{190}\) IR gas-filter correlation spectrometry was employed to measure methanol in vehicle exhaust.\(^\text{191}\) FTIR was employed for the remote analysis of CO, CO\(_2\) and methanol in motorboat exhausts.\(^\text{192}\)

The determination of methanol in the presence of ethanol can be carried out by GC\(^\text{193–195}\) and also by GC/FTIR and mass spectrometry (MS).\(^\text{196}\) The IR emission from a flame has been also proposed as a means for detection for LC to analyze mixtures of methanol, ethanol and propanol.\(^\text{197}\)

The filtering correlation function “compare” from Perkin Elmer has been proposed for the discrimination of spectra of mixtures of methanol and ethanol,\(^\text{198}\) and thermal lens spectrometry has been employed for the partial quantitative determination of methanol and ethanol in gaseous samples.\(^\text{199}\)

Kuehl and Crocombe\(^\text{200}\) have established a model for the quantitative analysis of methanol, ethanol and acetone in fermentation broth, showing that by using an ATR cell, synthetic mixtures of the three compounds under study can be analyzed with relative errors below 2%.

Garrigues et al.\(^\text{201}\) proposed a FTIR procedure for the direct determination of methanol and ethanol in liquid samples such as alcoholic beverages and eau-de-Cologne. It is based on vapor generation from small injected volumes of untreated samples into a heated Pyrex glass reactor in which ethanol and methanol are volatilized, at a temperature of 80 °C, and introduced into a long-path IR gas cell by means of a N\(_2\) carrier flow. The spectra obtained present two characteristic ethanol bands (1050 and 880 cm\(^{-1}\)) and a single characteristic methanol band (1030 cm\(^{-1}\)). The measurement of the area of the transient recording obtained for the wavenumber ranges 1025–950 and 950–820 cm\(^{-1}\) allows the determination of ethanol and methanol in the same sample by using a simple proportional equation approach. The limit of detection values found for an injection volume of 1 µL were 0.21% v/v for ethanol and 0.04% for methanol, and the relative standard deviation values were between 0.5 and 1.4% for five analyses of samples containing between 30–80% (v/v) ethanol and 0.5–3.5% (v/v) methanol. Acetone, ethyl acetate, 1-propanol and 2-propanol do not interfere with this determination when they are present at concentration levels of the order of those of methanol.

### 5.6 Fourier Transform Infrared Determination of Compounds in the Natural Environment

The standard protocol for oil and grease determination in polluted waters is a gravimetric procedure based on a liquid–liquid extraction (LLE) with Freon 113.\(^\text{202}\) The pioneering studies on IR spectrometric determination of oil and grease in waters were based on CCl\(_4\) extraction.\(^\text{203}\) However, the quantitative extraction of all types of oils like hydrocarbons, vegetable oils, animals fats, waxes, soaps, greases and related matter is difficult. Serious problems have been reported for the total extraction of several materials from waters, including gasoline, for which extraction yields of about 50% were found.\(^\text{204}\) The use of chlorinated hydrocarbons, like freon and CCl\(_4\), is undesirable because of their ozone-layer depleting effect.\(^\text{205}\) Thus it is an urgent task to search for alternative procedures for oil and grease extraction from waters.\(^\text{206,207}\)

The use of microwave ovens offers a fast way of improving analytical procedures that include a thermal step. Microwave-assisted procedures have been developed for sample digestion\(^\text{208}\) and derivatization.\(^\text{209}\) More recently, the use of a microwave-assisted technology has been proposed for the extraction of organic pollutants from sediments for their subsequent analysis by chromatography.\(^\text{210,211}\)

In 1997, Daghbouche et al.\(^\text{184}\) evaluated LLE, solid phase extraction and microwave-assisted extraction for FTIR spectrometric determination of oil and grease in polluted waters. A fast microwave-assisted quantitative procedure was proposed for the total extraction of oil and grease into CCl\(_4\) from water samples, with an irradiation time of 1 min, at an exit power of 520 W, using closed polytetrafluoroethylene (PTFE) vessels. The FTIR quantification of oils was carried out by the measurement of the area under the absorbance spectra in the range between 3058 and 2780 cm\(^{-1}\), using a baseline established between 3200 and 2700 cm\(^{-1}\). The analytical features of the method and those of LLE/FTIR spectrometry were evaluated and samples spiked with different types of oils examined.

The environmental impact of laboratory practices is not insignificant. Large amounts of toxic compounds are produced every day in research and application laboratories. The storage and destruction of dangerous pollutants contained in laboratory wastes needs adequate decontamination plants, and thus the elimination of waste is expensive and involves strict safety requirements. So it is necessary to substitute traditional methods by clean analytical technologies.\(^\text{121}\) FIA provides an interesting way to achieve reduction of reagent consumption and wastes. Using FIA/FTIR it is possible to offer an alternative to the traditional methods, providing a
drastic reduction of pollutant side effects. A semi-micro distillation unit was therefore incorporated into a simple FIA/FTIR manifold for the on-line recovery of the solvent used as carrier. This system was applied to the direct, simple and fast determination of ketoprofen, \(^{(124)}\) a nonsteroid anti-inflammatory drug with analgesic and antipyretic properties. \(^{(213)}\) The system permits a drastic reduction of reagent consumption and easy and fast sampling and cleaning of the measurement cell, as compared with the official method in the British Pharmacopoeia for ketoprofen determination, which is based on the measurement of the absorbance at 250 nm using methanol as solvent. \(^{(214)}\) For the quantification of ketoprofen in pharmaceuticals, the carbonyl bands at 1712 cm\(^{-1}\) and 1666 cm\(^{-1}\) were employed and the developed method provides a limit of detection of 0.04 mg ml\(^{-1}\) (3s) and a dynamic range which extends up to 10 mg ml\(^{-1}\). Typical coefficient of variation values ranged between 1.6 and 5%, with a sample injection frequency greater that 42 per hour. Accurate and precise results were obtained in the analysis of real pharmaceutical samples.

Another example of an important reduction in the side effects of analytical procedures is given by the quantification method of raw sugarcane sugars proposed by Cadet et al. \(^{(98)}\) which avoids the previous clarification of samples required by usual methods of sugar determination (HPLC, polarimetry, GC). This step of clarification needs a large quantity of lead acetate, a strong pollutant which, when released into the environment can pollute surface waters.

There are several methods proposed for the determination of carbonate and bicarbonate in waters, based on both instrumental and volumetric procedures. The official method is based on a simple titrimetric procedure, but a series of problems have been reported with the end-point determination and evaluation of titration data. \(^{(215)}\)

There are only few precedents for the IR determination of inorganic carbon in water by batch and FIA. One of these is that proposed for seawater analysis, based on batch acidification with H\(_2\)PO\(_4\) and colorimetric or IR determination of CO\(_2\) stripped with N\(_2\). \(^{(216)}\) Another is based on the use of a patent cylindrical thin-film reactor with an actively rotating inner cylinder and a central low-pressure mercury lamp. This allows the decomposition of the organic molecules through UV radiation and that of inorganic carbonates by acidification. The release of the CO\(_2\) is carried out by a N\(_2\) flow and its determination is done by IR. \(^{(216)}\) More recently, Pérez-Ponce et al. \(^{(217)}\) proposed the use of an electrically heated gas-permeation unit (GPU) for the vapor-generation FTIR of total carbonate in waters. The developed method is based on the simultaneous injection of 100 µL of sample and 100 µL of nitric acid in a two-channel manifold with a merging zone. This zone provides the generation of CO\(_2\) through the GPU, heated at 90°C, from which a stream of N\(_2\) sweeps the CO\(_2\) to a long-path IR gas cell. Absorbance measurements were made in the range from 2500 to 2150 cm\(^{-1}\) and the corresponding flow injection recordings were obtained as a function of time. The method provides a limit of detection of 4.6 ppm (expressed as mg of HCO\(_3^-\) L\(^{-1}\)) and a sampling frequency of 30 h\(^{-1}\). Results obtained for a series of natural waters compare well with those obtained by a titrimetric reference method.

More recently, these authors \(^{(14)}\) proposed a microwave-assisted vapor-generation FTIR spectrometric procedure for the determination of total carbonate in waters. The method is based on the simultaneous injection of 100 µL of sample and 300 µL of 0.1 M nitric acid into a two-channel manifold with a merging zone; a coil located inside a microwave oven favors the removal of CO\(_2\). The carbon dioxide is separated from the distilled water employed as a carrier, by means of gas–liquid separator, and is introduced by a nitrogen carrier flow inside a long-path IR absorption gas cell. This provides direct quantification of total carbonate concentration in the range up to 1000 mg HCO\(_3^-\) L\(^{-1}\) with a sampling frequency of 15 samples per hour. The procedure has a limit of detection of 15 mg HCO\(_3^-\) L\(^{-1}\) and a variation coefficient of 1.3% for five independent analyses.

5.7 Quantitative Fourier Transform Infrared Analysis of Compounds at Trace Levels

The use of FTIR for trace analysis is problematic, due to the lack of sensitivity of this technique and the use of small path length values. Substantial efforts were undertaken in order to improve the limit of detection of FTIR, e.g. by using alternative approaches such as the stopped-flow technique. \(^{(11,133)}\) Nevertheless they do not provide adequate solutions. Therefore other strategies have been investigated to increase the sensitivity of IR determinations.

The excellent results obtained by on-line preparative concentration of metallic elements by FA and atomic spectrometric techniques \(^{(218)}\) offers a model strategy for the improvement of the sensitivity of FTIR determinations. As an example for the determination of pesticides in waters, solid-phase extraction offers an excellent way for improving the limit of detection of FTIR. This strategy was selected because it allows easy on-line preparative concentration and does not require high volumes of organic solvents or the use of complicated phase-separation manifolds. \(^{(219–221)}\) Garrigues et al. \(^{(138)}\) proposed a new method for the FTIR determination of carbaryl, a pesticide found in natural waters which was
determined at 1746 cm\(^{-1}\). Their procedure permits (i) in-field sampling, (ii) stabilization of pesticides and (iii) fast determination of carbaryl. The sensitivity obtained with this procedure corresponds to 0.044 area units µg\(^{-1}\) cm\(^{-1}\) and with a limit of detection 15 µg L\(^{-1}\) of carbaryl, using C18 cartridges for preparative concentration and dichloromethane for on-line elution. The method could be applied to other types of components, providing new possibilities for the application of FTIR to trace analysis.

5.8 Other Fourier Transform Infrared Coupled Methods

SIA was introduced in 1990 by Ruzicka and Marshall\(^{222}\) and has improved classical FIA in many ways, especially concerning the drastic reduction of reagent consumed and waste generated and the robustness of the resulting analysis system. In classical FIA, the generation of different injection sequences would require a physical rearrangement of the FIA manifold for each sequence. This situation is different in the case of SIA, where only changes in the controlling software are required to create different interpenetrating dispersion profiles between samples and reagents. Schindler et al.\(^{171}\) employed for the simultaneous determination of glucose, fructose and sucrose in aqueous standards as well as in soft drinks using FTIR detection and multivariate PLS data analysis. Obtained results were compared with those found by an external reference method. Typical deviations from the results were of the order of 2.5%, 4.1% and 2.1% for glucose, fructose and sucrose respectively (Figure 10).

Vonach et al.\(^{135}\) proposed the modulation of the pH as a novel approach for the determination of phosphate with FIA and FTIR detection.

The use of FTIR as a detection system in HPLC is of particular interest in analytical chemistry. In particular, the fingerprint region around 1400–900 cm\(^{-1}\) provides valuable data for the confirmation of molecule structures, since most organic (and many inorganic) compounds exhibit strong and narrow absorption bands, providing a high degree of qualitative and structural information.

As has been indicated in previous sections, the coupling of HPLC and FTIR can be performed by using a standard flow cell, without mobile phase separation and by introducing an interface that evaporates the eluent and deposits the analytes into a medium compatible with FTIR detection. Another approach for solvent elimination, which is particularly interesting for aqueous solutions, is based on post-column on-line extraction. After extraction with chlorinated solvents (CH\(_2\)Cl\(_2\), CHCl\(_3\), CCL\(_4\)), various interfaces can be applied; regular flow cells,\(^{223,224}\) loading of the extracts on KBr, with subsequent DRIFT detection;\(^{225}\) or, more recently, deposition on a zinc selenide window by a spray jet assembly, followed by the analysis of the residues with a FTIR-microscope.\(^{176}\)

Vonach et al.\(^{135}\) used FTIR as a molecular-specific detection system for HPLC in an aqueous phase, and developed a method for sugar determination in beverages. The separation was achieved with an isotropic HPLC setup using an ion exchange column. The FTIR detection of the C–O bands in MIR, between 1000 and 1200 cm\(^{-1}\), was performed in real time with a 25 ml flow cell without elimination of solvent. Characteristic FTIR spectra of sucrose, glucose and fructose were recorded during the separation. The calibration of these sugars in the 5–100 mg mL\(^{-1}\) range resulted in a linear correlation with a standard deviation of the method of 0.11, 0.07 and 0.11 for sucrose, glucose and fructose respectively. The method was found also to be suitable for the identification and the quantification of minor components in beverages, such as taurine (4 mg mL\(^{-1}\)) and ethanol (0.4 mg mL\(^{-1}\)).

Lendl et al. in 1997\(^{226}\) developed a flow system containing a micromachined lamella-type porous silicon reaction and a novel MIR fiber-optic flow cell, which was used for the enzymatic determination of sucrose in aqueous solutions. The method relies on the enzymatic hydrolysis of sucrose catalysed by β-fructosidase and on the acquisition of FTIR spectra before and after complete reaction. The enzyme was covalently bound to the porous silicon reactor in a HF/ethanol mixture. For the measurement of small amounts of aqueous solution, a miniaturized flow cell was developed which consisted of two AgCl\(_x\)Br\(_{1-x}\) fiber tips (0.75 mm diameter) coaxially mounted in a PTFE block at a distance of 23 mm. The flowing stream was directed through the gap between the two fiber tips, which served to define the optical path length and to bring the focused MIR radiation to

---

**Figure 10** SIA/FTIR manifold: holding coil, 0.5 mm i.d., 250 cm; S1-3, standard solutions; W, water; mixing coil, 0.3 mm i.d., 30 cm. (Reproduced with permission from Lendl et al., *Analytical Chemistry*, 69(15), 2877–2881, © 1997, American Chemical Society.\(^{226}\))
the place of measurement. Using this set-up, a probed volume of about 10 nL was obtained. The calibration curve was linear up to 10 mmol\(^{-1}\) sucrose. Furthermore, the potential of this method was demonstrated by the analysis of binary sucrose/glucose mixtures showing no interference from glucose, and by the successful determination of sucrose in real samples (Figure 11).

The introduction of FTIR as a detector in miniaturized total analysis systems represents a significant step towards the development of techniques capable of obtaining molecular-specific information in miniaturized flowing streams. The huge amount of chemical information contained in FTIR spectra was exploited to reduce the number of enzymatic reactions needed for the determination of sucrose in aqueous standards as well as in real samples such as soft drinks. Both the development of a new molecular specific detector based on a miniaturized IR fiber optic flow cell and the application of a silicon micro-reactor with in-situ fabricated porous silicon layers as a surface-enlarging matrix for immobilized enzymes, can be considered as some of the most interesting uses of FTIR.

6 LIMITATIONS AND PERSPECTIVES OF INFRARED SPECTROSCOPY FOR QUANTITATIVE ANALYSIS

IR is probably the most significant range of the spectrum in order to provide an appropriate identification of a molecule and, because of that, IR spectrometry has been widely employed to confirm the nature of compounds and particularly to evaluate pure products.

However, the high absorption of IR radiation by water and the presence of a large number of characteristic bands for each functional group inside a molecule decreases sensitivity (notably with the use of small band-pass cells) and selectivity. These problems must be solved in order to obtain accurate quantitative data.

In addition to the pioneering studies carried out during the 1950s, the new age of quantitative analysis through IR spectrometry is based on two important developments in the field of analytical chemistry: chemometrics and FA.

Chemometrics has provided the mathematical tools to solve overlapping problems, which can be found in the interpretation of spectra in NIR and MIR, and to solve the serious problems presented by the influence of the sample environment in both the size and shape of the characteristic bands of analytes. As has been discussed in section 2, the use of multivariate calibration strategies, and specially PCR and PLS, provides the best way to solve these kinds of problems. It offers exciting possibilities for multicomponent determinations, through the use of a reduced number of previously analyzed samples as a calibration set and the prediction of sample concentrations. Through PCR and PLS data treatment it is possible to obtain accurate data for the concentration of several analytes in the same sample and also an estimation of physical properties.

The second milestone in the recent development of quantitative analysis by IR is the use of FA strategies, which improves sample introduction and method automation, and also reduces drastically the side effects of the use of IR-transparent solvents, which are frequently toxic. However, the main contribution of FA to the improvement of quantitative determinations by IR are the possibilities offered by the on-line coupling of derivatization procedures and especially for the on-line preparative concentration and elution of analytes. This increases drastically the limit of detection of the analytical procedures and offers an easy way to solve the problem of some matrix or intermolecular interference.
In the next few years there is expected to be a significant growth of the scientific literature on quantitative methods of determination by IR, both for trace analysis and for the screening of the main components of foods, biological and environmental samples. In this sense the new generation of low-cost FTIR instruments configured for NIR, MIR and FIR, and the development of new methodologies for direct sample analysis, will have a synergistic effect on the use of IR as a tool for routine analysis.

New developments in the remote sensing of air pollutants and recent advances in new strategies for enzymatic analysis and vapor generation-FTIR will be generalized in the following years. This will be achieved through the (i) introduction of fast and robust standardization methodologies, (ii) the use of enzymes in nonaqueous systems and (iii) the on-line treatment of solid samples for a fast screening of volatile organic compounds.

In short, we are at the beginning of a new area of vibrational spectrometry, which will clearly evidence and explore the possibilities of IR for quantitative determination of major, minor and trace components by incorporating the advances in chemometrics and automation.

A major concern which arises from the classification of spectral data, such as near-infrared (NIR) spectra, is that the number of variables often exceeds the number of cases. In this instance each spectrum represents a case or observation, and each variable corresponds to the wavelengths at which a response (e.g. reflectance) is measured. Classification refers to the process of assigning a spectrum whose class identity is unknown into one of several predefined classes. There are two main strategies for combating the high-dimensional (i.e. more variables than cases) scenario.

One strategy is to use a high-dimensional classifier, that is, one which is suited to the ill-posed nature of the data. The second strategy is to reduce the number of variables by a feature extraction method and supply the variables to a low-dimensional classifier, one which is suited to high observation-to-variable ratios. This article presents two high-dimensional classification methods – regularized discriminant analysis (RDA) and penalized discriminant analysis (PDA). The low-dimensional classifiers used include Bayesian linear discriminant analysis (BLDA), Bayesian quadratic discriminant analysis (BQDA), RDA and flexible discriminant analysis (FDA). Common stepwise selection routines are employed to investigate the effectiveness of the wavelet transform as a feature extraction technique. This includes implementation of the local discriminant bases (LDBs) algorithm and the adaptive wavelet algorithm (AWA).

1 INTRODUCTION

In this paper we investigate several strategies for classifying spectral data where the dimensionality or number of variables far exceeds the number of samples or objects. Such poorly posed data lead to a deterioration in performance of many standard classification techniques\(^1\). The presence of correlated variables can lead to a further deterioration in classification performance. Correlated data often result if the same response is measured at regular intervals in time or space. Although the techniques discussed in this paper can be applied to most highly correlated and highly dimensional data, such as time-varying signals, spectra and images, we focus our applications on the classification of NIR spectral data.

The discriminant problem when applied to NIR spectral data involves assigning an NIR spectrum whose class identity is unknown (Figure 1d) into one of the several predefined categories or classes. Figures 1(a), (b) and (c) show five sampled spectra from three different species of seagrass – *Halophila ovalis*, *Halodule uninervis/pinifolia* and *Halophila spinulosa*. The different species, which are referred to as species 1, 2 and 3 respectively, form the different group categories. A simple approach is to look for similarities between the unidentified spectrum and the spectra whose class identities are known. In this particular case this task is not straightforward, since the spectra from the different classes share similar characteristics. This problem highlights the relevance of automated discriminant methods for analyzing spectral data.

The general discriminant problem\(^2,3\) can be expressed as assigning a spectra, represented by the \(p\)-dimensional vector \(\mathbf{x} = (x_1, \ldots, x_p)^T\), into one of \(r \in \{1, \ldots, R\}\) classes. The assignment is performed by building a
set of transformed variables that remains relatively unexplored is wavelet coefficients. In this paper we investigate the potential of wavelet coefficients as features for discriminant analysis. Wavelet-based feature extraction methods involve two main procedures. The first procedure is the application of the discrete wavelet transform (DWT) to obtain the wavelet coefficients. The second procedure is the selection of a subset of wavelet coefficients to be supplied to the classification model.

Wavelet coefficients are considered useful because they can analyze different segments of data at different resolutions, thus enabling localized features in the spectra to be detected. These features can be extremely useful for discriminating purposes. Previous applications of wavelet-based feature extraction methods for classifying data are available.

The goal of this paper is not necessarily to find the best discriminant strategy, but to review some traditional methodologies and introduce the reader to some modern classification techniques, which have been divided into two groups:

1. classification of all the original data using a high-dimensional classifier
2. classification using a low-dimensional classifier where features are extracted from either the original data, or the DWT.

The paper proceeds by introducing the low- and high-dimensional classifiers in section 2. Section 3 discusses some feature extraction procedures and section 4 describes the DWT. Section 5 applies the different classification applications to four spectral data sets which exhibit different characteristics. Section 6 summarizes the classification results. Section 7 presents some guidelines for choosing classification techniques and concludes with some final remarks.

2 CLASSIFICATION METHODS

This section briefly describes the discriminant methods that were mentioned in section 1. The classifiers based on Bayes’s method are introduced first, followed by a description of the classifiers based on Fisher’s linear discriminant analysis (FLDA). Although FLDA is not applied in this article, the method is briefly reviewed as it is the foundation for FDA and PDA.

2.1 Bayesian Quadratic Discriminant Analysis

Bayes’s rule assigns a spectrum \( \mathbf{x} \) to the class \( r \in \{1, \ldots, R\} \), which maximizes the posterior probability,
as shown in Equation (1).

\[ P(r|x) = \frac{p(x|r)P(r)}{\sum_{r=1}^{R} p(x|r)P(r)} \quad \text{for } r = \{1, \ldots, R\} \quad (1) \]

Here, \( P(r) \) is the prior probability of belonging to class \( r \), and \( p(x|r) \) are the class probability densities, i.e. the probability of spectrum \( x \) arising from group \( r \). BQDA\(^2\)\(^3\) assumes that the class probability densities follow a multivariate normal distribution as shown in Equation (2).

\[ p(x|r) = \frac{1}{(2\pi)^{p/2}|S_r|^{-1/2}} \exp\left[-0.5(x - \bar{x}_r)^T S_r^{-1}(x - \bar{x}_r)\right] \quad (2) \]

where \( S_r = \frac{n_r}{n}(x_{ir} - \bar{x}_r)(x_{ir} - \bar{x}_r)^T/n_r \) is the covariance matrix of class \( r \), and \( \bar{x}_r = \frac{n_r}{n}x_{ir}/n_r \) is the mean vector of class \( r \). Both \( S_r \) and \( \bar{x}_r \) are sample estimates of the population class covariance matrices and mean vectors, respectively.

### 2.2 Bayesian Linear Discriminant Analysis

As with BQDA, BLDA\(^2\)\(^3\) also assumes that the class probability densities follow a multivariate normal distribution. BLDA makes the added assumption that the class covariance matrices in Equation (2) are equal, and are replaced with a pooled covariance matrix \( S_{pool} = \frac{1}{R} \sum_{r=1}^{R} n_r S_r/n \) to give Equation (3).

\[ p(x|r) = \frac{1}{(2\pi)^{p/2}|S_{pool}|^{-1/2}} \times \exp\left[-0.5(x - \bar{x}_r)^T S_{pool}^{-1}(x - \bar{x}_r)\right] \quad (3) \]

### 2.3 Regularized Discriminant Analysis

When the observation-to-variable ratio is small (e.g. less than three) the estimates of the class covariance matrices \( S_r \) become highly variable.\(^8\)

This can cause serious problems in the performance of the classification procedure. To overcome this phenomenon, Friedman\(^6\) has proposed one method of regularizing the class covariance matrix. RDA uses a similar classification rule to that shown in Equation (2) for BQDA. Instead of using the unbiased estimate of the class covariance matrix, RDA replaces \( S_r \) in Equation (2) with the regularized covariance matrix \( S_r(\lambda, \gamma) \) which undergoes a two-stage regularization procedure. Despite the possibility of slightly increasing bias, regularization can produce dramatic improvements in classification.\(^1\)\(^6\)

The first regularization procedure replaces the class covariance matrix with a linear combination of the class and pooled covariance matrices, as shown in Equation (4).

\[ S_r(\lambda) = (1 - \lambda)S_r + \lambda S_{pool} \quad (4) \]

The parameter \( \lambda \in [0, 1] \) controls the degree to which the pooled covariance matrix should be used. This form of regularization is similar to that which occurs when reverting from BQDA to BLDA. Replacing the class covariance matrix with the pooled covariance matrix reduces the number of parameters that have to be estimated. In fact, if \( \lambda = 1 \) then \( S_r(1) = S_{pool} \). The second regularization procedure is shown in Equation (5).

\[ S_r(\lambda, \gamma) = (1 - \gamma)S_r(\lambda) + \frac{\gamma}{d}\text{trace}[S_r(\lambda)]I \quad (5) \]

\( S_r(\lambda, \gamma) \) is adjusted by scaling the covariance matrices towards a multiplier of the identity matrix \( I \). The value of \( \gamma \in [0, 1] \) determines the degree to which \( S_{r,\gamma}(\lambda) \) is shrunk towards a multiplier of the identity matrix. Different \( \lambda \) and \( \gamma \) values ranging between 0 and 1 are trialled. The pair of values which produces the minimal risk of misclassification is used.

### 2.4 Fisher’s Linear Discriminant Analysis

Many pattern recognition methods are Bayesian- or Fisher-based techniques. The classifiers BLDA, BQDA and RDA are examples of Bayesian-based classifiers. Fisher-based classifiers stem from the time-honoured technique called FLDA. FDA and PDA, which are discussed in sections 2.5 and 2.6, respectively, are largely derived from FLDA.

As shown in Equation (6) FLDA assigns an object \( x \), to the class \( r \in \{1, \ldots, R\} \) which minimizes

\[ \|x^T - \bar{x}_r^T \|^2 \quad (6) \]

where \( V \) is a \( p \times s \) matrix whose \( i \)th column is the eigenvector \( v_i \) which corresponds to the \( i \)th largest eigenvalue of \( S_{W}^{-1} S_{B} \), and \( s \leq \min(R - 1, p) \). Here, \( S_B \) and \( S_W \) are the between- and within-covariance matrices of the data matrix \( X \), respectively. These are calculated from the training data using the definitions in Equations (7) and (8).

\[ S_B = \frac{1}{n} \sum_{r=1}^{R} n_r (x_{ir} - \bar{x}_r)(x_{ir} - \bar{x}_r)^T \quad (7) \]

\[ S_W = \frac{1}{n} \sum_{r=1}^{R} \sum_{i=1}^{n_r} (x_{ir} - \bar{x}_r)(x_{ir} - \bar{x}_r)^T \quad (8) \]

The solution for \( V \) arises from the formal discriminant problem as shown in Equation (9)

\[ \max v^T S_B v \quad (9) \]

subject to the constraint shown in Equation (10).

\[ v^T S_W v = 1 \quad (10) \]
2.5 Flexible Discriminant Analysis

FDA(7) is a nonlinear extension of FLDA which incorporates nonparametric regression methods to obtain nonlinear decision boundaries. The method of FDA is quite involved. For this reason we provide a very descriptive review of the method and refer the reader to Hastie et al.(7) and Mallet(8) for more refined details.

FLDA produces linear decision boundaries for separating objects from different classes. One way of producing nonlinear decision boundaries would be to expand the predictor matrix so that it includes quadratic and bilinear terms.(7) This would have the effect of producing discriminant boundaries which exhibit quadratic characteristics. A much more sophisticated approach is used by FDA to obtain much more flexible decision boundaries than quadratic forms.

The nonlinear decision boundaries in FDA are obtained by adaptively computing an expanded set of predictor variables by using nonparametric regression methods such as MARS (multivariate adaptive regression splines)(9) and bruto.(10) The new independent variables are computed with the aim of predicting the columns of a class indicator matrix. Hastie et al.(7) show that the regression coefficients are, by means of a linear transformation, equivalent to the matrix of eigenvectors (V) from FLDA. This relationship is neatly established by using optimal scoring as the link between regression analysis and FLDA (see also Breiman and Ihaka(11)).

2.6 Penalized Discriminant Analysis

PDA(12) follows a similar methodology to that used for FDA. That is, optimal scoring provides the link between regression and classification. The difference between FDA and PDA is in the regression method used. For FDA, the goal is to cater for situations where there is a high observation-to-variable ratio, and to produce flexible decision boundaries for classification. This is achieved by using adaptive regression methods such as MARS and bruto. The goal of PDA is to cater for situations where there is a low observation-to-variable ratio, and also for data containing large amounts of highly correlated variables such as spectra, signals and images. It becomes obvious that the regression methods used by PDA will differ from the regression methods used by FDA. The regression methods for PDA need to be suited to extreme dimensionalities and be somewhat resistant to multicollinearities. Consequently, PDA uses penalized least squares regression (PLSR) methods. Ridge regression(13) can be seen as a trivial PLSR method.

The use of penalized regression methods can be made equivalent to a penalized discriminant method by solving Equation (9) subject to the constraint

$$v^T(S_w + \Omega)v = 1$$

where $\Omega$ is a penalty matrix which helps prevent overfitting and other computational instabilities.

3 FEATURE EXTRACTION

Feature extraction(2,3) is a dimensionality reduction procedure that selects a subset of $p_*$ variables from a much larger set of $p$ variables. Typically, the dimensionality $p_*$ of the subset of feature variables is less than $p$, and usually very much less than the number of observations, $n$. The main goal of feature extraction relative to this article is to extract as much relevant discriminatory information from the data as possible, while simultaneously eliminating redundant features which do not contribute to or have an adverse effect on the classification procedure. It is recommended that some form of feature extraction be implemented prior to the application of low-dimensional pattern classification methods.

The feature extraction procedure may involve selecting features from either the original (untransformed) data, or from data which has been transformed. Hence, feature extraction can consist of two main components – feature selection and feature transformation. These topics are explained in sections 3.1 and 3.2 respectively.

3.1 Feature Selection

Feature selection procedures select a subset of features or variables from the data. Features can be selected from the original data, also referred to as a variable selection, or from data which have been preprocessed or transformed in some other way. When feature selection is from the original data, the feature transformation is via the identity matrix.

One commonly used feature selection criterion for classification is the ratio of the between-to-within variability.(14) That is, for each variable, the between-variability divided by the within-variability is calculated and the variables that produce large values of this quotient are selected, and used as input to the classifier. This measure of between-to-within-variability is referred to as Fisher’s criterion.(15) Other feature selection criteria commonly used include the Mahalanobis distance and Wilk’s lambda.(16)

One criterion which is applied later in this article is the quadratic probability measure (QPM).(17) Since the QPM is a probabilistic measure, $0 \leq \text{QPM} \leq 1$. Ideally, larger values of the QPM are preferred, since this suggests that the classes can be differentiated with a higher
SPECTRAL DATA, MODERN CLASSIFICATION METHODS FOR

degree of certainty. The QPM is formulated as shown in Equation (11)

\[ QPM = \frac{1}{n} \sum_{i=1}^{n} a_Q(i) \]  

(11)

where \( a_Q(i) \) is defined as shown in Equation (12).

\[ a_Q(i) = \frac{1}{2} \left[ P(r|x_{i,r}) - \frac{1}{2} \sum_{r=1}^{R} P(r|x) \right]^2 \]  

(12)

In section 5 we use a leave-one-out cross-validated quadratic probability measure (CVQPM). Here, the parameters in the appreciation score \( a_Q(i) \) are computed in the absence of \( x_i \).

It is worthwhile to give some consideration to procedures that can be used for selecting combinations of variables. For example, two features chosen separately may produce less favourable results than two features chosen in combination. With high-dimensional data it is not realistic to perform an exhaustive search of every possible combination of variables. In this case, stepwise methods can be useful. A forward stepwise search sequentially incorporates variables into the discriminant procedure that contribute to the discrimination power of the model. Generally, variables cease to enter the model when little or no change to the performance of the discriminant model is registered. Conversely, a backward stepwise search removes variables from the model until the performance of the model begins to deteriorate. In the presence of high-dimensional data, it is not advisable to use a backward stepwise search, since initially all the variables will be fed to the classifier, which will lead to ill- and poorly-posed situations, not to mention the computational expense and the numerical instabilities which are likely to arise. If desired, a backward selection scheme could be used, following the implementation of a forward, stepwise selection method.

3.2 Feature Transformation

The procedure for calculating a new set of features is called feature transformation. Examples of spectral features that may be informative include the heights, positions or shapes of peaks. Other features commonly used include principal components and Fourier coefficients, while more recently wavelet coefficients have been investigated. These features are obtained by a transformation called the DWT.

The advantage of using features from the wavelet transform, as opposed to principal components, is that the DWT takes into consideration the ordering or incrementation of the variables. This order information is not contained in the principal components. An alternative procedure is Fourier transform (FT) which does this ordering into consideration, but offers a broader, more global description of a spectrum or signal. The DWT is able to break the spectra into pieces at different scales and analyze the frequency content of each piece. This allows the DWT to convey localized frequency information about a spectrum, and such information can be quite useful for classification purposes.

4 WAVELET TRANSFORMS OF DISCRETE DATA

4.1 Discrete Wavelet Transform

Consider the finite length, discretely sampled spectrum \( x = (x_1, x_2, \ldots, x_{p-2}) \) of dimensionality \( p = 2^J \) for some \( J \in \mathbb{Z}^+ \). The DWT for such a spectrum can be likened to a series of filtering operations. There are various procedures such as zero padding which can be implemented if \( p \neq 2^J \) (see Bruce and Gao and Mistri). The raw spectrum \( x \), which we also call \( c_0 \) for ease of notation, passes through a lowpass L and a highpass H filter to produce the decimated sequences \( c_{j-1} \) and \( d_{j-1} \), each of dimensionality \( 2^{j-1} \). The scaling coefficients \( c \) are the outputs from the lowpass filter, and the wavelet coefficients \( d \) are the outputs from the highpass filter. The subscript \( j \in \{0, 1, \ldots, J\} \) indicates which level the coefficients are from in the DWT, with \( J \) being the highest level. The general procedure for the DWT continues by passing the scaling coefficients \( c_j \) at level \( j \) through a lowpass and a highpass filter to produce the scaling \( c_{j-1} \) and wavelet coefficients \( d_{j-1} \) at the next lower level \( j-1 \). The scaling and wavelet coefficients at the lowest level \( j_0 \) in the DWT, as well as the wavelet coefficients at higher levels, comprise the DWT. That is, the DWT contains the coefficients \( c_{j_0}, d_{j_0}, d_{j_0+1}, \ldots, d_{j_1} \). Because of the decimation procedure which forms part of the filtering operations, the number of scaling and wavelet coefficients halve when moving from one level to the next lower level of the DWT, so that the dimensionality of the scaling or wavelet coefficients at some level \( j \) is \( 2^j \).

The filtering operations from any level \( j \) to \( j-1 \) can be defined by the matrix operations

\[ c_{j-1} = L_j c_j \]

\[ d_{j-1} = H_j c_j \]

In summation notation this can be written as shown in Equations (13) and (14)

\[ c_{j-1,i} = \sum_{k=0}^{N_j-1} \xi_k c_{j,2i+k} \]  

(13)

\[ d_{j-1,i} = \sum_{k=0}^{N_j-1} h_k c_{j,2i+k} \]  

(14)
where there are \( N_f \) lowpass \((\ell_k)\) and highpass \((h_k)\) filter coefficients, respectively. In this discussion periodic boundary conditions were assumed.

\[
c_{j,k} = c_{j,2^j+k}
\]

\[
d_{j,k} = d_{j,2^j+k}
\]

Figure 2 indicates how the wavelet coefficients and scaling coefficients are calculated for some discrete spectrum \( x = (x_0, \ldots, x_T)^T = (c_{3,0}, \ldots, c_{3,7})^T = c_3 \) of length \( p = 8 \). Obviously, in practice the dimensionality of spectra will usually be much greater than \( p = 8 \). This example is to simply present the underlying principle of the DWT. Initially, all the data \( c_3 \), are passed through the low- and highpass filters to give the scaling \( c_2 = (c_{2,0}, \ldots, c_{2,3})^T \) and wavelet \( d_2 = (d_{2,0}, \ldots, d_{2,3})^T \) coefficients at the next lower level. As one progresses down the tree, the number of elements in each of the bands is reduced by half.

If for example \( N_f = 2 \), then the lowpass filter coefficient matrices would be defined as in Equations (15–17).

\[
L_3 = \begin{pmatrix} \ell_0 & \ell_1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & \ell_1 & \ell_0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & \ell_1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & \ell_0 & \ell_1 \end{pmatrix}
\]

(15)

\[
L_2 = \begin{pmatrix} \ell_0 & \ell_1 & 0 & 0 \\ 0 & 0 & \ell_0 & \ell_1 \end{pmatrix}
\]

(16)

\[
L_1 = (\ell_0, \ell_1)
\]

(17)

Likewise, the highpass filter coefficient matrices would have the same structure as the \( L_3 \), \( L_2 \) and \( L_1 \) matrices, the main difference being \( \ell_i \) would be substituted with \( h_i \).

For future reference, band \((j, r)\) will indicate the \( r \)th band at the \( j \)th level of the DWT. The band at the top of the tree is then band \((3,0)\). The bands at the next lower level, are band \((2,0)\) and band \((2,1)\). The scaling coefficients at some level \( j \) will be contained in band \((j,0)\), and the wavelet coefficients at the same level will be stored in band \((j,1)\).

Figure 3 shows the effect of performing the DWT on an artificially generated spectrum. The spectrum contains 256 points and consists of a sine curve with a period of 2, sampled over \(-\pi\) to \(\pi\), a block pulse, and another sine curve which has a period of 5 over the same interval \(-\pi\) to \(\pi\). For display purposes only, the DWT is shown for the first six levels \( j = 8, 7, 6, 5, 4, 3 \). The original spectrum in band \((8,0)\) undergoes a lowpass filtering process to give the scaling coefficients in band \((7,0)\). The original spectrum also undergoes the highpass filtering process to give the wavelet coefficients which lie in band \((7,1)\).

Next, the scaling coefficients in band \((7,0)\) are passed through the lowpass and highpass filters to give the scaling coefficients in band \((6,0)\) and the wavelet coefficients in band \((6,1)\). The same procedure continues with the scaling coefficients from band \((6,0)\) being filtered to give the scaling coefficients in band \((5,0)\) and the wavelet coefficients in band \((5,1)\). This process could continue for \( \log_2 256 = 8 \) levels, in which case there would be one scaling coefficient and one wavelet coefficient.

As one moves down the tree, the filtered signals in the scaling bands become smoother and smoother. The lowpass filtering process can be likened to a smoothing procedure followed by decimation (i.e. subsampling). The wavelet bands highlight the information which has not been captured by the scaling bands.

The components with the highest frequency are the first to be removed from the scaling coefficients and captured by the wavelet coefficients. Consider for example the scaling coefficients in band \((5,0)\) – the remains of the \( \sin(5t) \) are almost undetected in the scaling coefficients, whereas the coefficients of the \( \sin(2t) \) curve are more perceptible. The most noticeable feature in the lower scaling levels of the tree is due to the low-frequency event of the block pulse.

### 4.2 Wavelet Packet Transform

So far we have only considered filtering the scaling coefficients, but it seems perfectly plausible to filter the wavelet coefficients. The wavelet packet transform (WPT) is obtained by filtering both the scaling and wavelet coefficients.

The WPT has a tree-like structure, where each band in the transform produces two new children bands at the next lower level. The tree-like structure occurs because the detailed (or wavelet) coefficients are filtered through a lowpass and a highpass filter to obtain the next lower level of the WPT. This is done in the same way that the smoothed (or scaling coefficients) are filtered. It is convenient if we introduce the notation \( x^j_l(\tau) \)
Figure 3 Two-band DWT performed on a generated spectrum to level 3.

...to represent the wavelet packet coefficients (WPCs) which occur at the \(j\)th level in the \(r\)th band of the decomposition.

Figure 4 presents the structure of a WPT for some discretely sampled signal \(x = (x_0, x_1, \ldots, x_{2^J})^T = x^{[J]}(0)\). The \((J-1)\) level of the WPT would be obtained as for the DWT, that is the data are passed through a lowpass and a highpass filter so that

\[
x^{[J-1]}(0) = L_J x^{[J]}(0)
\]

\[
x^{[J-1]}(1) = H_J x^{[J]}(0)
\]
For the WPT, the number of bands doubles from one level to the next (lower) level, since each of the bands in the previous level is passed through a lowpass and a highpass filter. At the next level, there will be four bands of WPCs which are obtained by
\[
\begin{align*}
\mathbf{x}^{[j-2]}(0) &= \mathbf{L}_j \mathbf{x}^{[j-1]}(0) \\
\mathbf{x}^{[j-2]}(1) &= \mathbf{H}_j \mathbf{x}^{[j-1]}(0) \\
\mathbf{x}^{[j-2]}(2) &= \mathbf{L}_j \mathbf{x}^{[j-1]}(1) \\
\mathbf{x}^{[j-2]}(3) &= \mathbf{H}_j \mathbf{x}^{[j-1]}(1)
\end{align*}
\]
The same procedure may continue until there is one WPC in each of the bands. In general, \( \mathbf{x}^{[j]}(0) = \mathbf{e}_j \) and \( \mathbf{x}^{[j]}(1) = \mathbf{d}_j \).

4.3 Local Discriminant Basis Algorithm
The local discriminant basis (LDB) algorithm of Saito and Coifman\(^{(15)}\) selects coefficients from the WPT and then uses these coefficients for classification. The selection of the coefficients involves several steps. The first step is to perform the WPT for each object \( \mathbf{x}_{ir} \) for \( i = 1, \ldots, n, \quad r = 1, \ldots, R \). Saito and Coifman\(^{(15)}\) then calculate what they refer to as an “energy map”. This is done for each class \( r = 1, \ldots, R \). The energy maps have the same structure as the WPT, hence the same indices are used to locate items within the energy map (or tree). If \( \mathbf{e}_{ir}(\tau) \) denotes the energy coefficients in band \((j, \tau)\) of the energy map for class \( r \), then Equation (18) represents the sum of squares of the coefficients that occur in the same position of the wavelet packet tree divided by a normalization constant.
\[
\mathbf{e}_{ir}^{[j]}(\tau) = \frac{\text{diag} \left( \sum_{i=1}^{n_r} \mathbf{x}_{ir}^{[j]}(\tau) \right) \mathbf{x}_{ir}^{[j]}(\tau)^T}{\text{const}}
\]
The energy maps are obtained from the data objects that belong to class \( r \). The notation \( \mathbf{x}_{ir}(\tau) \) refers to the WPCs in band \((j, \tau)\) of the WPT produced from the object vector \( \mathbf{x}_{ir} \).

Once the energy maps have been constructed for each class, Coifman\(^{(15)}\) apply the best basis algorithm\(^{(26)}\) to find an optimal tree. This involves selecting bands of coefficients which run horizontally across the WPT without overlapping vertically, i.e. no band can lie directly beneath or above another band. In the case of the LDB algorithm, this set of bands should collectively maximize some discriminant criterion \( \mathcal{U} \).

To find the bands of the optimal tree, one starts at the lowest level \( j_0 \) in the WPT and works up. Initially, the criterion measures for each of the bands of coefficients at level \( j_0 + 1 \) are compared with the criterion measures for the bands of the coefficients in the descendants at level \( j_0 \). If the criterion measure of the parent node is superior to that of the descendant nodes then the descendant nodes are deleted. If the descendant nodes produce a superior criterion measure then the descendant nodes are kept and the parent node is deleted. This procedure continues all the way to the top of the tree and the optimal tree consists of the bands that were not deleted in the elimination process.

A symmetric entropy discriminant criterion\(^{(10)}\) is used in section 5 to measure the distinctness of the bands, as shown in Equation (19)
\[
\mathcal{U}(j, \tau) = E_{\text{sym}} \mathbf{e}_{i1}^{[j]}(\tau), \ldots, \mathbf{e}_{iR}^{[j]}(\tau) = \sum_{l} \sum_{r \neq l} E \mathbf{e}_{i1}^{[j]}(\tau), \mathbf{e}_{i1}^{[j]}(\tau) + E \mathbf{e}_{i1}^{[j]}(\tau), \mathbf{e}_{ir}^{[j]}(\tau)
\]
where \( E(\mathbf{w}, \mathbf{g}) \) is calculated as shown in Equation (20)
\[
E(\mathbf{w}, \mathbf{g}) = \sum_{i=1}^{p} w_i \log \frac{w_i}{g_i}
\]
and \( p = \text{length}(\mathbf{w}) = \text{length}(\mathbf{g}) \). Here, \( \mathbf{w} \) and \( \mathbf{g} \) are two vectors whose similarity (or dissimilarity) is to be quantified. The entropy measure requires \( w_i = g_i = 1 \).

Once the optimal tree has been found, it is necessary to choose a subset of the WPCs, since the number of WPCs corresponding to the best basis is still equal to the dimensionality of the original data vector. Saito and Coifman\(^{(15)}\) mention that one way of selecting a subset
is to choose the WPCs from the optimal tree that have the largest ratio of between-groups variance to within-groups variance, as described in section 3. Alternatively, one could select the WPCs based on another criterion, such as the entropy criterion.

4.4 Adaptive Wavelet Algorithm

There are several “off-the-shelf” wavelets that are defined by their respective filter coefficients. These include, for example, the Daubechies wavelets, coiflets, symlets and the Meyer and Haar wavelets (see for example Daubechies\(^{(2)}\)). An initial problem is to decide which set (or family) of filter coefficients will produce the best results for a particular application. In practice, several families of filter coefficients may be trialled, and the family that produces the most desirable results is used. It can be advantageous however, to design your own task-specific filter coefficients rather than using a predefined set. The AWA of Mallet et al.\(^{(21)}\) avoids the need to preselect a family of filter coefficients. In Mallet et al.,\(^{(21)}\) the filter coefficients are designed with the aim of assigning objects to their respective classes with the greatest degree of accuracy.

4.4.1 m-Band Discrete Wavelet Transform

The AWA is presently based on the DWT rather than the WPT, but uses the more general m-band DWT \((m \geq 2, \ m \in \mathbb{Z}^+\) where there is one lowpass filter, and \(m - 1\) highpass filters. We prefer to have the dimensionality \(p = m^{(j - 1)}\) and set \(J = \lfloor \log p / \log m \rfloor\). A three-band DWT for the spectrum \(x = (x_0, x_1, \ldots, x_8)\) is shown in Figure 5. There is one lowpass filter and two highpass filters, producing one set of scaling (or smoothed) coefficients and two sets of wavelet (or detailed) coefficients, respectively. As before, to traverse from one level to the next, only the scaling coefficients are filtered and the number of coefficients in each band is reduced by a factor of \(m = 3\).

The filtering operations for the general \(m\)-band DWT from some level \(j\) to level \(j - 1\) can be described by the matrix operations

\[
\begin{align*}
\mathbf{c}_{j-1} & = \mathbf{L}_j \mathbf{c}_j \\
\mathbf{d}_{j-1}^{(z)} & = \mathbf{H}_j^{(z)} \mathbf{c}_j \\
& \quad z = 1, \ldots, m - 1
\end{align*}
\]

In summation notation one has Equations (21) and (22)

\[
\begin{align*}
\mathbf{c}_{j-1,i} & = \sum_{k=0}^{N_f-1} \ell_k \mathbf{c}_{j,mi+k} \\
\mathbf{d}_{j-1,i}^{(z)} & = \sum_{k=0}^{N_f-1} h_k^{(z)} \mathbf{c}_{j,mi+k} \\
& \quad z = 1, \ldots, m - 1
\end{align*}
\]

where it is assumed

\[
\begin{align*}
\mathbf{c}_{j,k} & = \mathbf{c}_{j,mv+k} \\
\mathbf{d}_{j,k}^{(z)} & = \mathbf{d}_{j,mv+k}^{(z)}
\end{align*}
\]

Following the same notation as introduced earlier, band\((j, \tau)\) will be referred to as the \(\tau\)th band at the \(j\)th level of the DWT. The band at the top of the tree in Figure 5 is band\((2,0)\). At the next level the bands from left to right are referred to as band\((1,0)\), band\((1,1)\) and band\((1,2)\). Similarly, the bands in the last level of the DWT are band\((0,0)\), band\((0,1)\) and band\((0,2)\).

The AWA provides one way of generating suitable filter coefficients for performing the \(m\)-band DWT \((m \geq 2)\). This is done by placing constraints on the filter coefficients and then searching for suitable filter coefficients that satisfy these constraints. More details on the \(m\)-band DWT are available in the literature.\(^{(5,28,29)}\)

4.4.2 Filter Coefficient Conditions

There are restrictions imposed on the filter coefficients so that a two-band (or higher) DWT or WPT can be performed. The adaptive wavelet should also adhere to these conditions. Let \(\mathbf{A}\) denote the \(m \times N_f\) matrix, with the first row containing the lowpass filter coefficients and the remaining \(m - 1\) rows containing the sets of highpass filter coefficients, as shown in Equation (23).

\[
\mathbf{A} = \begin{bmatrix}
\ell_0 & \ell_1 & \cdots & \ell_{N_f-1} \\
h_0^{(1)} & h_1^{(1)} & \cdots & h_{N_f-1}^{(1)} \\
\vdots & \vdots & \ddots & \vdots \\
h_0^{(m-1)} & h_1^{(m-1)} & \cdots & h_{N_f-1}^{(m-1)}
\end{bmatrix}
\]

(23)

\(\mathbf{A}\) can be partitioned into \(q + 1, m \times m\) sub-matrices as follows: \(\mathbf{A} = (\mathbf{A}_0, \mathbf{A}_1, \ldots, \mathbf{A}_q)\). The conditions imposed on

![Figure 5 A three-band DWT.](image-url)
the filter coefficients so that an orthogonal wavelet basis exists can be summarized as follows,

1. Orthogonality: \( k A_k A_{k+i}^T = \delta_{ii} I \), where \( \delta_{ii} = 1 \) if \( i = 0 \), and zero otherwise, and \( I \) is the identity matrix.
2. Regularity: \( k \ell_k = \sqrt{m} \).
3. The Lawton matrix condition, \( M_{ij} = \ell_k \ell_{k+j-mi} \), must have 1 as a simple eigenvalue.

(More sophisticated wavelet and scaling functions will satisfy additional conditions.)

The AWA attempts to find the elements of \( A \) which optimize the discriminant problem at hand. Instead of optimizing over each filter coefficient in \( A \), the AWA makes use of the factorized form\(^{21,30,31}\) of a wavelet matrix and the conditions placed therein to reduce the number of parameters to be optimized. It can be shown\(^{31}\) that \( A \) can be constructed from some set of normalized vectors denoted by \( u_1, \ldots, u_q \) and \( v \), where the total number of parameters to be optimized is \( N_f - 1 \).

5 APPLICATIONS

5.1 Data Sets

Four spectral data sets were used to investigate the various classification procedures. Each data set initially contained 512 variables (i.e. \( p = 512 \)). The data sets are referred to as the seagrass, mineral, \( p \)-xylene and butanol data sets. The number of training and testing spectra in the group categories is listed in Table 1 for each set of data. Sample spectra from each of these data sets are presented in Figures 6–9.

5.2 Methodology

There are many different classification and feature extraction strategies that can be applied to spectral data.

Figure 8 Five sample spectra from the \textit{p}-xylene data.
Collectively, the term strategy refers to the particular classifier utilized, such as RDA, or a feature extraction technique. A strategy may even refer to the combination of feature extraction methods with a particular classifier. The classification strategies are described in the following sections.

5.2.1 Stepwise Bayesian Linear and Quadratic Discriminant Analysis

A stepwise feature selection method is used to select variables from the original data set. These selected variables then undergo BLDA and BQDA. If the stepwise feature selection procedure is used in combination with BLDA, the classification strategy is referred to as SBLDA (stepwise Bayesian linear discriminant analysis). Likewise, if BQDA is the classifier then the procedure is called SBQDA (stepwise Bayesian quadratic discriminant analysis).

The stepwise procedure considered here starts with an empty subset, and at each step adds the variable (or wavelength) that produces the largest increase in the CVQPM. The procedure ceases to enter variables into the model when one of the following stopping criteria is reached.

- The change in the correct classification rate (CCR) is less than $1/n$, where $n$ is the number of samples in the data set. That is, from one iteration to the next, the inclusion of another variable does not improve the CCR by more than $1/n$.
- The CCR reaches 100%.

The results of the stepwise strategies for both SBLDA and SBQDA are summarized in Table 2. SBLDA produced a higher test CCR for the seagrass and p-xylene data, while SBQDA produced a higher test CCR for the mineral and butanol data. The butanol data set posed the greatest challenge for the stepwise procedures.

5.2.2 Flexible and Penalized Discriminant Analysis

The regression method used for FDA was bruto. Bruto is an additive regression model which computes the terms in the model using smoothing splines. The bruto procedures also accommodate a feature selection routine. The regression method used for PDA was ridge regression. Both FDA and PDA were applied to the original data sets without prior feature selection. FDA, when used in conjunction with bruto, can be seen as a monothetic method since, while it is initially supplied with all of the variables, it eventually selects a much smaller subset. PDA (and RDA) on the other hand can be seen as polythetic methods, since all of the variables are entered into the final model. The classification results for FDA and PDA are displayed in Table 3. For all data sets except for the mineral data, FDA outperformed PDA in terms of the misclassification rate of the test data. Again the
butanol data set was the more challenging data set to classify, especially for PDA.

5.2.3 Regularized Discriminant Analysis

RDA was applied to each data set with 25 different \((\lambda, \gamma)\) combinations. The combinations resulted from each pairwise combination of the settings 0.00, 0.25, 0.50, 0.75 and 1.00. Table 4 presents the training and test classification rates for each data set as well as the corresponding \((\lambda, \gamma)\) grid settings that were used to produce the respective classification rates. Again, reasonable classification rates were experienced for the seagrass and mineral data. Of interest however is the fact that all of the spectra from the training and testing p-xylene data were correctly classified using RDA. From previous applications, the p-xylene data (along with the butanol data) posed a challenge for many of the classification strategies.

The \((\lambda, \gamma) = (1.00, 0.25)\) setting was found to be optimal for the seagrass, mineral and butanol data sets. This indicates that for these data sets a pooled covariance matrix is preferred to one that is not pooled. The combination \((\lambda, \gamma) = (0.25, 0.25)\) was used for the p-xylene data set, as it weights the individual class covariance matrices more heavily than the pooled class covariance matrix.

5.2.4 Banded Bayesian Linear and Quadratic Discriminant Analysis

Perhaps the simplest strategy to incorporate wavelet-based methods with classification strategies is to choose a family of filter coefficients, perform the DWT, and then supply all the coefficients from some band \((j, t)\) to a classifier. The term “coefficients” is used loosely to refer to either wavelet or scaling coefficients. We used the \(m = 2\) band DWT with \(N_T = 16\) filter coefficients from the Daubechies family. The classifiers used were BLDA and BQDA. Since these are low-dimensional methods, the number of coefficients in band \((j, t)\) should be small when compared with the sample size, so that an ill- or poorly-posed situation is avoided. The banded approach is a very simple procedure for feature selection of the wavelet coefficients. Previously, Bos and Vrieling(18) used a similar approach, except that the bands of coefficients were supplied to neural networks. The coefficients from band \((3,0), \text{band}(3,1), \text{band}(4,0)\) and \(\text{band}(4,1)\) were supplied to the classifiers.

The terms BBLDA (banded Bayesian linear discriminant analysis) and BBQDA (banded Bayesian quadratic discriminant analysis) are adapted if the bands of coefficients are supplied to BLDA or BQDA, respectively. The classification results for BBLDA and BBQDA are summarized in Tables 5 and 6 respectively. The wavelet bands tended to dominate for BBLDA for the mineral, p-xylene and butanol data sets. For BBQDA, numerical

| Table 3 Percentage of correctly classified objects for FDA and PDA |
|----------------------|------------------|------------------|
| Data                |FDA | PDA         |
| Seagrass Train      | 98.18| 96.97       |

| Table 6 Classification results for BBQDA |
|-------------------------------|------------------|------------------|------------------|------------------|
| Data                          | \(X_j^1(0)\) | \(X_j^1(1)\) | \(X_j^2(0)\) | \(X_j^2(1)\) |
| Seagrass Train                | 100 | 100 | 100 | 100 |
| Test                          | 100 | 99.02 | 100 | 100 |
| Mineral Train                 | 100 | 96 | – | – |
| Test                          | 93 | 96 | – | – |
| p-Xylene Train                | 88 | 86.67 | 100 | 100 |
| Test                          | 66.67 | 72.00 | 81.33 | 76.00 |
| Butanol Train                 | 89.58 | 87.50 | 100 | 100 |
| Test                          | 74.47 | 72.34 | 63.83 | 57.45 |

The numbers in the square brackets are the level of the transform.
instabilities arose for the mineral data when 16 coefficients were supplied to the classifier. This can be attributed to the fact that, for BQDA, the class sample size should be large compared with the dimensionality. For the mineral data there are 20 objects per class, which is only marginally larger than the number of coefficients (16), hence it was not possible to produce accurate results for this setting.

5.2.5 Stepwise Feature Extraction from the Discrete Wavelet Transform

A more sophisticated procedure for incorporating wavelet-based methodologies with classification strategies is to use a stepwise selection procedure to select the coefficients which are to be supplied to the respective classifier. As for the banded procedures described in the previous section, the two-band DWT is performed to level 3 using a Daubechies wavelet defined by 16 filter coefficients. The bands shaded in grey in Figure 10 indicate the total set of bands from which wavelet or scaling coefficients may be selected from the stepwise procedure. The same stepwise routine used for SBLDA and SBQDA is also applied here to the coefficients $c_1, d_1, d_2, \ldots, d_8$. If the coefficients are supplied to BLDA we refer to this classification procedure as SWBLDA, and when the classifier is BQDA the procedure is referred to as SWBQDA.

Also indicated in Figure 10 are the coefficients selected by SWBLDA (asterisk) and SWBQDA (circle). It should be noted that for the challenging $p$-xylene and butanol data sets there are more coefficients selected from higher levels in the DWT, indicating that the classifiers are discriminating using information relating to high-frequency events. For the seagrass and mineral data, however, it should be noted that the classifiers select coefficients from the lower levels, and in fact some scaling coefficients are selected, indicating that information relating to the basic shape of the mineral and seagrass data has been utilized.

The classification results for SWBLDA and SWBQDA are shown in Table 7. The $p$-xylene data set is the only data set which gives a higher test CCR using SWBQDA as opposed to SWBLDA. Whilst SWBLDA does outperform SWBQDA for three of the four data sets in terms of the test misclassification rate, SWBLDA is often outperformed by other classification strategies. SWBLDA does however compare favorably with other classification strategies when applied to the butanol data.

5.2.6 Local Discriminant Basis

LDB adds even greater sophistication than the stepwise and banded procedures for combining wavelet features and classification methods. In this section the WPT (with $m = 2$) was calculated to level 3 using the Daubechies

![Figure 10](image-url) Coefficients selected from the DWT by stepwise wavelet feature extraction using Bayesian linear discriminant analysis (SWBLDA) (asterisks) and stepwise wavelet feature extraction using Bayesian quadratic discriminant analysis (SWBQDA) (circles).
